A PRELIMINARY NOTE ON THE ACTION AND USES OF PSEUDO-EPHEDRINE.

By R. N. CHOPRA, M.A., M. (Cantab.),

LIEUTENANT-COLONEL, I.C.S.,

B. B. DIKSHIT, M.B., B.S., D.P.H.,

and

K. VENKATACHALAM PILLAI, M.A., M.S. (Mad.).

(From the Department of Pharmacology, School of Tropical Medicine and Hygiene, Calcutta.)

A few drugs of recent years have attracted so much the attention of the medical profession as ephedrine—an alkaloid from *E. vulgaris*, the Chinese plant Ma Huang. A considerable volume of experimental work has been done on this subject and the well compiled bibliography by Professor B. E. Read will interest those who wish for further details. The drug has been in use in China for the last five thousand years. The habitat of ephedra, however, is not confined to China but has a much wider geographical distribution. A reference to the map prepared by Liu will show that it is scattered widely all over the world. In India a number of species grow abundantly in the drier regions of the Himalayas. A few species of ephedra also grow in the plains but these contain little or no alkaloid.

The plant has not been used in the indigenous medicine in this country, though according to Aitchison some parts of *E. vulgaris* are used medicinally in Lahoul, though not mentioned in the Ayurvedic (Hindu) or Tibbi (Mohammedan) medicine. It is said that one variety of ephedra, probably *E. intermedia*, is the famous "soma" plant from which the favourite drink of the Rishis (ascetics) of the Vedic period was prepared, but there is little evidence to support this statement. The gradual increasing use of ephedrine in therapeutics and its high price induced us to explore the reserves of the Indian varieties of ephedra and to study their chemical composition, pharmacologic action and clinical uses. As the retail price of ephedrine at present is about 800 rupees per pound, we also investigated the sister alkaloid pseudo-ephedrine to see if any use could be made of it in therapeutics.

Watt (1890) describes the species of ephedra growing in India.

1. *Ephedra vulgaris* Ris (fl. Br. India), also known as *E. gerardiana* Wal, *E. distachya* and *E. monostachya* (Linn); is known in the vernaculars by the names *ahina*, *chema*, *butshur*, *khandu*, *khana*, *kunawar*, *phok* in different parts of India.

It is a small, low growing rigid shrub which occurs throughout the Himalayas. It grows in abundance in the dry, stony regions of the temperate and Alpine Himalayas extending from

Western Tibet to Sikkim. On the Shalai Hills, North of Simla, it occurs in large quantities at an altitude close on 10,000 ft.

2. *Ephedra pachyclada* Boiss, also known as *E. intermedia* Schrenk and Mey. It is known as "hum" or "huma" in Persian, "gehma" in Bombay and "oman" in Pushtu. It is a tall shrub found in the dry, stony regions of the Western Himalayas and Western Tibet.

3. *E. peduncularis* Boiss, also called *E. alte*, Brand, *E. alata*, Myers. It is known in the vernacular as *kuchan*, *nikkikuran*, *bratta*, *tandala*, *lastuk*, *mangarival*, *bandukai di*. It is a tall scandent shrub with slender branches which grows on stony ground in Sind, the Punjab and Rajputana.

Besides these three varieties described by Watt, two more of lesser importance grow in various parts of India. (Chopra, Ghosh and Dutt, 1928). They are (1) *E. foliata* Boiss (fl. Orient), and (2) *E. fragilis* (flowering plants of Beluchistan. I. H. Burkill). These latter varieties are uncommon.

Chopra and his collaborators (1929) describe two varieties of ephedra growing side by side on the mountain ranges bordering on the Jhelum Valley. These varieties are of special interest on account of their high alkaloidal yield. The proportion of ephedrine and pseudo-ephedrine, however, in the two varies greatly:—

1. *E. intermedia* variety *tibetica* which gives an alkaloidal content ranging from 0.2 to 1.0 per cent., of which 0.025 to 0.056 is ephedrine and the remainder is pseudo-ephedrine.

2. *E. vulgaris* or *E. gerardiana* which has an alkaloidal content of 0.8 to 1.4 per cent. of which about half is ephedrine and the balance is pseudo-ephedrine. It may also be noted here that there are marked variations in the alkaloidal content of the green twigs and the stems of these varieties. The alkaloidal content of the green twigs of the Indian *E. vulgaris* is about four times that present in the stems and that of *E. intermedia* nearly six times.

The following table gives the results of the analysis of a number of varieties of Indian ephedra we have investigated. The alkaloid was chiefly obtained from the green twigs and stems of the plant. The berries, roots and branches contain very little alkaloid. From the study of the seasonal variation which we have been carrying out, it is found that during autumn before the winter frost sets in, the alkaloidal yield is maximum.

The alkaloids were isolated by extraction with 80 per cent. alcohol, with or without previous treatment with lime or Na_2CO_3 . The separation of ephedrine and pseudo-ephedrine was effected by the simple method accidentally discovered by Read and Feng when attempting to free the crude alkaloid from the coloured impurities by washing with chloroform. These workers found that after washing with chloroform the residue free from coloured impurities was practically pure ephedrine hydrochloride and that the

Fig. (b).—Upper tracing, respiration; middle, kidney volume; and lower, carotid B.P. Note marked increase in the kidney volume corresponding to the rise in carotid B.P. Respiration shows relaxation of the bronchioles.

Fig. (c).—Upper tracing, spleen volume, middle, carotid B.P.; and lower, record of drops of urine. Note the marked contraction in the spleen volume and increase in the flow of urine.

Fig. (d).—Upper tracing, B.P. in the femoral vein; lower tracing, carotid B.P. Note the increase in pressure in the vein corresponding to the increased B.P. in the carotid artery.

contraction in the size of the spleen resembling that obtained by adrenalin.

The volume of other abdominal viscera such as the kidneys shows an increase after an injection of the drug (Graph II, fig. b). These effects are produced by general rise of blood-pressure all over the body produced by the vasoconstricting action of the drug which forces the blood into the splanchnic area. It is also to be noted that the increase in the volume of the kidney corresponds to the increase in the systemic blood-pressure; when this falls to normal, the kidney volume also becomes normal.

The increase in the volume of the kidney suggested that the alkaloid might have a diuretic action; the urine flow was, therefore, measured by putting a cannula into the ureter. Graph II, fig. (c), shows the effects of an injection of pseudo-ephedrine on the kidney secretion; the drops of urine emerging from the cannula were recorded on the drum by an electro-magnet. It is quite clear that the rate of secretion is markedly increased and it was also noted that the acceleration of the urine flow lasted as long as the blood-pressure effect lasted.

Therapeutic uses of pseudo-ephedrine.

We have already remarked that even under the best of conditions the yield of ephedrine from different varieties of ephedra growing in this country does not exceed 50 per cent. of the total alkaloids and ephedrine is a very expensive drug even now, though its price has been reduced from Rs. 1,100 per pound to Rs. 800 per pound. Some of the Indian varieties contain large quantities of pseudo-ephedrine and little ephedrine. In view of these facts we tried to see how far it was possible to substitute pseudo-ephedrine for ephedrine. The senior author has been using a liquid extract, made from both *E. vulgaris* and *E. intermedia*, for some time in the treatment of asthma with good results. The extract is prepared by exhausting the dried powdered twigs with 90 per cent. alcohol, sufficient water being then added to make the strength of alcohol about 45 per cent. 5 c.c. of the extract contain $\frac{1}{2}$ gr. of the alkaloids. He has also tried this preparation as a cardiac stimulant and, though in both cases the series of patients was not large, the results were encouraging. The extract produced a well marked beneficial effect when administered to patients in whom the action of the heart was weak and compensation was failing. Our observations on a number of patients showed that there was a definite rise of blood-pressure amounting to 10 to 20 mm. of Hg. after 60 minim doses of the extract of ephedra were given three times a day. Marked diuresis was produced in those patients in whom the function of the kidneys was disturbed from inefficient circulation.

We have also used the pure alkaloid pseudo-ephedrine for the relief of attacks of asthma in place of ephedrine with excellent results. Within 15 minutes to half an hour of the oral adminis-

tration of $\frac{1}{2}$ gr. of this drug, the feeling of tightness round the chest is relieved and the patient's breathing becomes normal. A similar dose, taken when the premonitions of an attack are felt, generally stops the paroxysm.

Ephedrine is a powerful alkaloid and our experience with its use in the treatment of asthma has not been altogether satisfactory. It undoubtedly controls the paroxysm and relieves the symptoms in 15 minutes to half an hour, but it is likely to produce unpleasant side-effects. We have noticed in some patients acute pain in the cardiac region lasting 10 to 20 minutes. A feeling of distress in the præcordium is not an uncommon symptom in a large number of cases. Patients may also complain of palpitation, flushing of the skin and tingling and numbness of extremities and tachycardia may be produced. In patients with organic disease of the heart it may produce decompensation. Besides this the stimulating effect of the alkaloid on the sympathetic is liable to produce constipation which aggravates certain types of asthma. Loss of appetite is not infrequently produced. This drug has not been in use sufficiently long for us to know all its untoward and toxic effects but we have evidence that they do exist. Caution is, therefore, recommended in its use especially for prolonged periods in the treatment of such diseases as asthma. Its routine use in controlling paroxysms is to be deprecated.

The action of pseudo-ephedrine on the sympathetic is not so powerful as that of ephedrine but its bronchodilator action appears to be quite marked. It relieves paroxysms of asthma almost as quickly as ephedrine but we have not yet tried it in a sufficiently large number of patients to come to any definite conclusion regarding its side effects. The results so far have been encouraging, and the side effects as judged from our small series of patients are not so unpleasant as those of ephedrine. If the use of this alkaloid is extended in the treatment of asthma and other conditions for which ephedrine is being used, not only will the cost of treatment be reduced but it may also be possible to avoid some of the unpleasant side effects of the latter drug. The use of an alcoholic extract made from ephedra will still further reduce the price and make it accessible for all classes of patients.

Summary and Conclusions.

- (1) Pseudo-ephedrine occurs in most of the Indian varieties of ephedra in large quantities.
- (2) The pharmacological action of pseudo-ephedrine closely resembles its isomer ephedrine, the difference being only a question of degree.
- (3) As ephedrine is an expensive alkaloid costing Rs. 800 per pound, pseudo-ephedrine was tried clinically in such conditions as asthma, failing heart, etc., with encouraging results.
- (4) Ephedrine gives rise to unpleasant side effects. Although the series of cases in which pseudo-ephedrine was tried is small the unpleasant side effects were not so prominent as is the case with ephedrine.

(5) A liquid alcoholic extract prepared from crude ephedrine has been successfully used in therapeutics in place of the purified alkaloids.

Both the ephedrine and pseudo-ephedrine used are articles of Indian manufacture and alkaloids of excellent quality are manufactured from the Indian varieties of ephedra and sold by the Bengal Chemical and Pharmaceutical Works and the Union Drug Co. of Calcutta. The latter firm has put an alcoholic extract of ephedra on the market.

THE CONTINUOUS ADMINISTRATION OF SALINE PER RECTUM.

By A. H. PROCTOR, M.D., M.S., F.R.C.S.E.,

LIEUTENANT-COLONEL, I.M.S.,

Presidency General Hospital, Calcutta.

TWENTY years ago J. B. Murphy wrote regarding appendicitis, "We have treated on this plan forty-seven consecutive cases of peritonitis, of the direct perforative type, with two deaths, one, the sixteenth case, of a double pneumonia six days after operation, long after all peritoneal symptoms had subsided, the other, the forty-fifth case, died on the fourth day from an intestinal obstruction due to the twisting of the ileum around the omentum, which was adherent to an old hernial opening." (Keen's Surgery, Vol. IV, p. 789).

To-day at two of the leading hospitals in England, these cases have a mortality of 20 per cent. and 29 per cent. against Murphy's 4.25 per cent. (Recent advances in Surgery, p. 291). Assuming Murphy's figures to be correct, the only possible explanation is some radical difference in the treatment. Now the essential factor in Murphy's treatment was the prolonged administration of normal saline and calcium chloride solution per rectum.

Every surgeon will be prepared to swear that he also uses continuous saline per rectum in these cases. It would probably be nearer the truth if he said he prescribed it.

How often does the nurse report that the saline was stopped, because the patient started to reject it after three or four pints had been given?

In one large hospital, I am told, they have given up rectal saline in favour of subcutaneous saline, a route which has obvious limitations.

A reference to the standard text-books on nursing, would lead any one to suppose that the

details Murphy insists on, are not essential, and both by surgeons and nurses there has been a general failure to grasp his principles. These principles are two, namely:—

I. That the saline shall be administered at the rate of absorption, so that at no time is the rectum distended with fluid.

II. That there shall be, at all times, a free outlet for flatus. The object is the same, to avoid the distension of the rectum.

Distension is the normal stimulus to the rectum to empty itself, and if the flatus has not a free outlet, it will be forced by the side of the rectal tube into the bed. In its passage it is accompanied by the fluid contents of the rectum, and further administration is stopped, because the patient is considered to be rejecting the saline. If the flatus cannot escape past the rectal tube it passes back up the colon and disturbs the quiescence of the bowel, which is so essential for recovery. At the same time it causes pain and discomfort which is attributed to the proctoclysis, and provides another excuse for stopping the saline.

Murphy's technique naturally observed these principles, but it was always difficult for nurses to manage satisfactorily. Either the can was placed too low and the patient only received an intermittent supply, or it was placed too high and the bed was flooded. Murphy's description indeed is open to the criticism that it fixed an arbitrary position for the reservoir, and a varying head of fluid depending on whether the reservoir was full or nearly empty. The temptation to regulate the flow by droppers, clamps, or by altering the position of the reservoir was irresistible.

Certain modifications of Murphy's technique, which do not violate his principles, have overcome the difficulties. Two simple experiments will enable the essential points to be grasped by the nurse in charge.

Experiment I.

Take the barrels of two four-ounce glass syringes and connect them up with a length of rubber tubing about four feet in length. Call one "A" and let it represent the rectum. The other "B" represents the supply funnel. Holding them on the same level fill them with water until they are half full. Now keeping "A" fixed move "B" up and down. It will be noted that as "B" moves up the level of the water in relation to the top of the funnel moves down, and vice versa. The level of the fluid in fact remains stationary, depending on the level of the fluid in "A," which represents the rectum in actual life. In other words all that we need to do, to determine the level of a pool of fluid in the rectum, is to connect it by a tube to a funnel, and fix the funnel so that the level of the fluid shows in the funnel.

Experiment II.

Bring "A" and "B" close together, letting the tube hang down in a loop. Blow down "A"

and estimate the effort required to blow air out through "B." Then straighten the loop by separating the funnels to the maximum without kinks, and try again. Repeat the experiment after introducing a dropper or a clamp as is commonly done to regulate the flow.

It is at once obvious that loops, clamps, droppers, etc., are adequate obstacles to the return of flatus. The practical application of these observations is as follows:—

A cylindrical funnel, such as the glass funnel of an army pattern salvarsan apparatus or the barrel of a four-ounce syringe, is connected up with the rectal nozzle. The whole apparatus is now filled with saline solution so that when the rectal nozzle is held level with the middle of the funnel the solution is just bubbling over the tip of the nozzle.

The funnel is now lowered in relation to the nozzle, and the latter inserted into the rectum.

The funnel is raised and four to six ounces more fluid run into the rectum. The funnel is now carefully raised and lowered until we ascertain the position where the fluid just half fills the funnel. It is fixed at this point, and any loops or kinks straightened out. The level of the fluid is now exactly the same as the level of the pool in the rectum, and if correctly adjusted rises and falls with respiration. Now above the funnel we suspend a heated reservoir or vacuum flask containing the bulk of the saline solution. Leading from it is a tube and dropper, by means of which the solution can be dropped at any required rate into the open mouth of the funnel. The rate of flow is accurately determined by

measuring the quantity into an ounce measure, and taking the time.

At present the supply funnel is being kept warm by means of a hot water bag wrapped round it. A more satisfactory arrangement is to have an electrically heated section of piping between the funnel and the rectal nozzle. This section of pipe, however, must be straight and not in the form of a spiral as is usual in such apparatus. Attention may profitably be called to other points that were insisted upon by Murphy.

The nozzle should be a vaginal hard rubber or glass tip, flexed at an obtuse angle two inches from the tip, and having numerous openings. It should be inserted so that the angle fits closely to the sphincter and the tube is then bound firmly to the thigh with adhesive plaster so that it may not be expelled. Many books recommend a rubber catheter and that it be passed as far as possible into the rectum. This is wrong. Murphy insisted on numerous openings and that it be passed only as far as the obtuse angle, that is, for two inches.

The rate of flow should be such that it requires not less than forty nor more than sixty minutes for a pint and a half of the solution to percolate into the rectum. The proctoclysis should usually be continued for three days, rarely as long as five or six. The solution he used was normal saline with one drachm to the pint of calcium chloride. Murphy recommended the administration of a pint and a half every two hours. At the same time he advocated a rate of flow of a pint and a half in one hour. It is presumed, therefore, that he gave his patients alternate hours of rest, except in the severer cases, for he quotes the case of a child of eleven absorbing thirty pints in twenty-four hours. From personal experience I am satisfied that a strict adherence to Murphy's methods produces better results than those quoted from "Recent advances on Surgery" at the beginning of this note.

N.B.—Murphy's technique has been given above. In practice at the Presidency General Hospital we use isotonic saline and glucose solution and a somewhat slower rate of flow approximately $\frac{2}{3}$ to 1 pint per hour.

CÆSAREAN SECTION. SOME TYPES AND THEIR USES.

By S. A. McSWINEY, B.A., M.B., B.Ch., F.R.C.S.I.,
MAJOR, I.M.S.,
*Professor of Clinical Obstetrics (Offg.), Medical College,
Calcutta, and Second Surgeon, Eden Hospital,
Calcutta.*

I. THE CLASSICAL CÆSAREAN SECTION.

THIS is the best known, the simplest and is still the most commonly practised type. Its uses be within certain well-defined limits and, therefore, it will be discussed in some detail. The technique varies somewhat in different centres: that described below is the one which has been found most useful in this hospital.

The abdomen is opened, after passing the catheter, by a median (or paramedian) incision between the symphysis and the umbilicus about 5—6 inches long: the exact length depends on the amount of fat on the abdominal wall, but it must allow of an incision 4—5 inches long in the uterus. The incision in the abdominal wall must be carefully made because the latter is often surprisingly thin. The uterus is then "centred"; it is to be remembered that the uterus is normally tilted a little to the right and rotated to the right, and therefore, it is wise to "centre" it before incising it. Swabs are then packed around to prevent blood and liquor amnii from escaping into the peritoneal cavity: the uterus is incised in line with the skin incision. This incision in the uterus is slowly and gradually deepened along its whole length. The operator must not be flurried by the bleeding which may be very free nor should any time be wasted in trying to pick up bleeding points: they will stop when the uterus is empty. Care must be taken not to cut the baby. (If the placenta is in front, the bleeding will certainly be free. It should be either pushed aside or incised). When the membranes are opened, there will be a rush of liquor amnii. The fingers should be slipped into the uterus and by guarding the baby with them, the incision can be rapidly completed. The first assistant hooks his finger into the upper angle of the uterine incision and keeps the uterus hitched up close to the abdominal wall so as to lessen the spill of blood and liquor amnii into the peritoneal cavity. The child is grasped by the leg and delivered: a second assistant clamps and cuts the cord and takes charge of the baby. (The baby is usually under the influence of the anæsthetic, therefore, no undue anxiety need be felt if it does not cry lustily at once: nor should any but the gentlest methods of artificial respiration be used. Any other methods are always dangerous and here they are useless as well as dangerous). The first assistant now delivers the uterus outside the abdomen: 1 c.cm. of pituitrin is injected into the uterus itself. (Some operators prefer to inject it into the mother's deltoid just as the operation is commenced.) Hot towels are wrapped around the uterus and, if the hæmorrhage is excessive, the assistant slips his hand into the pouch of Douglas and grasps the cervix to control the bleeding. The placenta is then delivered into the wound and the membranes are carefully peeled off by gauze pressure.

Suturing of the uterus is then carried out in two layers as follows:—the first layer is of strong silkworm-gut, 1 cm. apart; this picks up all the layers except the mucous membrane. The second layer of No. 1 catgut is continuous; this picks up peritoneum and a very little muscle so as to "Lembert" completely the first layer. The suture material is of importance. Catgut is commonly recommended throughout. It is not reliable in the process of auto-digestion that goes on in the involuting

uterus and is likely to leave a weak scar. Silk might be used, as recommended by Spencer, but is more likely to absorb sepsis spreading through the mucous membrane. No case of rupture of the scar from one of our cases has been reported, although many have been through succeeding pregnancies, and, what is the supreme test, some have been through succeeding labours.

The utero-vesical and Douglas's pouches are swabbed clear of blood-clot and the omentum is brought down behind the uterus. The patient is sterilized by cutting and tying the tubes, if it is considered necessary, and the abdomen is closed in layers.

This operation, if carried out by an operator of average skill and in suitable surroundings, is attended with a low death-rate, provided that it is done *before, or just at the onset of labour*. The mortality in such cases is estimated to be 1.6 to 1.8 per cent. by Eardley Holland(1) in his masterly survey of 3374 Cæsarean sections done in Great Britain and Ireland. A survey by Gordon(2) of 1805 Cæsarean sections performed in America, shows a higher mortality—3.5 per cent. for cases not in labour and 6.4 per cent. for cases early in labour, i.e., within six hours of the onset of labour.

The great simplicity and the comparative safety of section when done at the proper time and place, should not be the excuse for doing it unnecessarily. It has been aptly said that any fool can do a Cæsarean section but, that it takes a wise man to know when to do it. Fitzgibbon points out that a 1.6 per cent. mortality is more than three times the total mortality of child-birth and adds: "with what must be looked upon at present as the inevitable mortality of Cæsarean section, I consider it essential to avoid performing the operation upon any case capable of safe delivery by the natural passages."(3). Unfortunately, the subject is not so simple and uncomplicated as it might appear, nor is every obstetrician as careful and conscientious as Fitzgibbon. Polak, in a discussion on operative obstetrics in America, recently said: "...other operators have so widened the indications for Cæsarean section that this method is being employed for no real obstetric reason, simply because it is the quickest, most convenient way of getting the baby out of the uterus." Most illuminating figures of the frequency of sections were collected from various hospitals in America in 1925 by Dr. Tottenham(4) who was then on his way to take up the Professorship of Obstetrics in Hong Kong. They show an amazing discrepancy and are as follows:—

Jefferson Hospital Philadelphia		1	Cæsarean to	6 deliveries.
Boston Lying-in Hospital	1	"	"	12
Bellevue Hospital, New York	1	"	"	97
Johns Hopkins Hospital	1	"	"	125
Swedish Hospital Minneapolis	1	"	"	201
New York Lying-in Hospital	1	"	"	585
Burnside Hospital Toronto	1	"	"	861

There cannot possibly be such a difference in the physique of the women in Philadelphia and Toronto to account for the difference between 1 to 6 and 1 to 861! The difference is rather, in the obstetrical skill and care of the medical attendants.

The public is even more gullible about Cæsarean sections than about most things, and it never fails to be thrilled by the operation which is, to them, intensely dramatic. If a doctor expends the most meticulous care and patience on a woman during a long and tedious labour and gives her a live baby through the natural passages, he will be considered to have done only what any midwife could have done and he will be given the usual confinement fee: whereas, if he had walked into an operating theatre at an hour and date suited to his convenience and done the section (which would mean about half an hour's work devoid of anxiety), his name would be mentioned with bated breath in half the houses in the town, and—this of course had not affected his judgment—the fee willingly given to such a superman, would be three times his usual confinement fee. The public is firmly convinced, that the man who does the most sections, is not the worst obstetrician but manifestly the best. They do not realise, that a woman who has once had a Cæsarean section done and escaped its dangers, subjects the scar to a very severe test in each succeeding pregnancy and labour—a danger which is a very real one. George Bernard Shaw states that the public is absurd in the reliance it places on the rectitude of the medical profession: he says that if a bridge is unsafe, the opinion of one expert is taken about its lack of safety and its destruction is handed over to another. But, if a leg has to come off, the public foolishly asks the man who is to take it off for his opinion as to whether it should come off or not. If for amputation of the leg, one substitutes Cæsarean section, the remark would be more apt and pointed.

Most obstetricians know of sections done for all manner of inadequate reasons: I have heard of one, the indication for which was that the lady—who had quite a roomy pelvis—had no legal right to have a baby at all! An example of another unnecessary section is given in the following case which is so instructive of the amount of meddlesome midwifery that occurs, that no apology is made for quoting it at some length:—

Ch., Hindu, aged 30 years, 7th gravida, was admitted to the Eden Hospital on 4th May 1925 at midnight. Last period August 1924. Her obstetrical history, given by her relative—a medical man—was:—the first four pregnancies ended in craniotomies: the fifth in Cæsarean section at term in 1921: the sixth in a premature labour and natural delivery at 8 months. "She is now brought for another craniotomy" he casually explained to me. Labour was said to have begun at 6 p.m. on the 4th May and the mem-

branes ruptured some hours later. When seen by me, at 2 a.m. on the 5th May, her condition was as follows:—

Condition good. T. 99.8. P. 96. Uterus, size of full term. Vertex R.O.P. F.H.S. 148. Measurements:—7 inches, interspinous: 9 inches, intercrystal: external conjugate, 7 inches: transverse diameter of the outlet, 4 inches. P. V., os fully dilated: anterior lip oedematous; no bag of membranes: vertex presenting: very slight caput; no disparity between the size of the head and the pelvis discoverable by Munro Kerr's manœuvre: diagonal conjugate $4\frac{1}{4}$ inches. The head and anterior shoulder were rotated manually to convert it into R.O.A. presentation and a binder was applied. At 9 a.m. the head had gone down into the pelvis. I applied the forceps and a live baby, weighing 7 lbs. 13 ozs. was delivered easily! The mother and baby left the hospital quite well on 14th of May. When one realises that this baby weighed two pounds more than the average Bengali baby and that it was delivered by easy forceps after 15 hours labour, one wonders what the indication was for the Cæsarean section and the ghastly succession of craniotomies. My own theory is, that the latter were instances of meddlesome midwifery and that the section was done hurriedly, without a careful examination, on account of the dreadful tale of woe of the previous labours.

The decision to do a section or not, should be arrived at as a result of a cool, calm and deliberate judgment. Extreme degrees of contraction are not likely to be overlooked by the average medical man and the decision offers no difficulty: the difficult cases are those with minor degrees of contraction, and these are the cases which are often overlooked until a difficulty arises during delivery. Here again, one should remember that Fitzgibbon states that 75 per cent. of all cases of medium and minor degrees of contracted pelvis will deliver themselves. A patient told me recently that she was to have been delivered by Cæsarean section of her first baby, but that she had the baby so easily and quickly, that there was no time to perform the operation! The baby weighed 9 lbs.

The question of a test labour or Cæsarean section, arises in these borderline cases. A careful examination under an anæsthetic is always a wise and often a necessary procedure. The points in favour of a test labour are:—youth and good health of the patient: measurements not much below normal: i.e., true conjugate 4 inches— $3\frac{1}{2}$ inches: no marked disparity between the size of the head and the pelvis by Munro Kerr's manœuvre, (the parietal boss should not overlap the anterior edge of the symphysis): premature onset of labour: anterior vertex lie of the child: good pains if labour has started (or a history of them in previous labours): and softness of the cervix. The points that weigh down the scales in favour of section are:—constitutional disease or toxæmia of the mother: bad obstetrical history: ad-

vanced age of the patient: measurements well below normal, i.e., true conjugate below 3½ inches: marked disparity between the head and the pelvis as shown by Munro Kerr's manœuvre: malpresentation or posterior lie of the vertex: weak pains or a history of primary uterine inertia: rigidity of the cervix and, lastly, if the patient desires to be sterilized. Two factors are impossible to estimate before labour, without a previous history. They are (a) the strength with which the uterus will contract and (b) the ease with which the cervix will dilate. Primary uterine inertia is much commoner in India than in England and, when it is associated with a rigid cervix and early rupture of the membranes, it causes one the greatest anxiety. It is particularly common in squat, shortnecked, stout women—they often have a uterus like a paper bag.

What is a test labour? This varies with the ideas of different obstetricians but, in as much as some strong pains in the second stage are usually required to drive the head in a doubtful case into the pelvis, a test labour should be allowed to progress long enough for some contractions in the second stage to take place.

If a test labour has been decided upon and fails after a fair trial, or if one sees the patient for the first time, only after she has been in labour for many hours or days and the membranes have ruptured many hours before, then the time for the classical Cæsarean section has passed, and its performance is fraught with great danger. This is proved by Eardley Holland's figures as follows:—

	Per cent.
Mortality in cases operated on before the onset of labour	1·6
Mortality in cases operated on early in labour ..	1·9
" " " , after attempts at induction ..	14
" " " " , unsuccessful attempts with forceps ..	25
Mortality of cases operated on after unsuccessful attempts at craniotomy	50

These figures show that the classical section should be done only before, or very early in labour, and that every hour in labour spells danger, which increases by leaps and bounds as a result of attempts at induction, forceps application and craniotomy.

The extremely valuable work by Harris and Browne(5) confirms the above. These workers took cultures, by the abdominal route, from the lower uterine segment in 50 consecutive Cæsareans at Johns Hopkins Hospital. They proved:—

(a) That the uterus was sterile if the section was done before labour and before rupture of the membranes.

(b) That out of 29 cases less than six hours in labour the uterus was sterile in 28, whereas in 21 cases more than six hours in labour the uterus was infected in all.

(c) That the uterus was infected in all cases in which the membranes had ruptured.

(d) That the uterus was infected in all cases in which vaginal examinations had been done.

These are the cases which call for the second type of Cæsarean section, i.e., the lower uterine segment type.

II. THE LOWER UTERINE SEGMENT CÆSAREAN SECTION.

The names of two authorities are associated with this type, i.e., Munro Kerr and De Lee. Their methods are different and must be carefully distinguished.

The technique of Munro Kerr(6) is as follows:—

The vagina is sterilized as carefully as possible and the abdomen is opened by a median (or paramedian) incision, 6 inches long, from the symphysis upwards. Doyen's retractor is inserted and the exposed area of the uterus is carefully packed off. The peritoneum is incised transversely 1 inch below its loose attachment to the uterus and an upper and lower flap of peritoneum are raised up. The lower flap with the bladder is retracted downwards. The lower uterine segment is opened by a slightly curved transverse incision, convexity downwards, (carefully made because the wall here is very thin). The hand inserted into the uterus directs the head out of the wound: the assistant, by making pressure on the fundus and sides, helps to direct the baby out of the uterus. (Occasionally forceps may be applied to the head). The placenta is delivered out of the wound if the cervix is not well dilated, or, if the cervix is well dilated, the placenta is delivered into the vagina after closure of the abdomen. The cut edges of the uterus are held by sponge-holding forceps and sewn up with catgut in three layers. Lastly, the peritoneum is overlapped over the uterine incision, covering it securely and the abdomen is closed. A drain may be left in the lower angle of the wound if necessary.

De Lee's method differs from the above in two points:—

(a) The bladder is separated from the lower uterine segment and retracted downwards, and (b) the incision into the lower segment is longitudinal and not transverse. He claims that this means (a) less bleeding from the uterus and no danger of opening a large vessel at the side of the uterus (which may happen with a transverse incision), (b) a greater bar to the leakage of sepsis out of the uterus is provided by not merely a fold of peritoneum—as in Munro Kerr's method,—but by replacing the bladder over the uterine incision, (c) better facilities for draining later on if necessary, through an anterior colpotomy wound, (d) a more secure scar, which is less strained during a subsequent pregnancy and labour.

An objection to De Lee's section is, that the lower uterine segment must be well dilated by labour, otherwise the upper end of the vertical uterine incision may extend into the upper uterine

segment. Munro Kerr's section however, can easily be done irrespective of whether the patient has been in labour or not. A full and beautifully illustrated description of De Lee's Cæsarean section is to be found in his text-book of obstetrics. The abdomen is opened as in Munro Kerr's section and a retractor is inserted as above. Briefly the chief points are that, after the peritoneum is incised transversely and an upper and lower flap raised up, the bladder is then separated from the lower uterine segment by finger and gauze pressure. The bladder is then retracted downwards and the lower uterine segment is opened by a longitudinal incision. The hand inserted into the uterus rotates the head to bring the face into the wound. The face is then helped out of the wound by forceps or manipulation and the rest of the baby follows. The placenta is delivered into the wound and the membranes are wiped off by gauze pressure. If bleeding from the uterus is free, it is plugged with gauze which is led into the vagina. The uterine wound is sewn up in three layers with interrupted catgut sutures. The bladder is replaced over the wound and the peritoneal flaps are overlapped and sewn up. The abdomen is then closed.

In the lower segment type of operation, nothing should come into the field of the operation except the lower part of the uterus. There is, therefore, very little soiling of the peritoneum. A great advance has, therefore, taken place by providing for late cases, a method which is very much safer than the classical method. Stein and Leventhal(7) have published a record of 32 cases which had test labours and which were afterwards delivered by the lower uterine segment incision. The mortality was nil: the shortest time in labour was twelve hours and the longest 66 hours, the average being 29.8 hours. Danfort and Greer(8) similarly have reported 30 cases safely delivered by this method after having test labours averaging 21.7 hours. Most authorities agree that this new method should displace the classical operation in cases of doubtful infection, and some authorities are so enthusiastic that they urge the complete abandonment of the classical operation in favour of the lower uterine segment section in all cases. It is not yet possible to compare the results of the one with the other. The former is often performed in unsuitable surroundings (and perhaps on unsuitable occasions) by many men who make no claim to being specialists: the latter has been performed so far, only by specialists who have suitable operating theatres, etc., at their disposal: nor has the lower segment operation been in wide use long enough to collect complete figures of rupture of the scar. De Lee(9) states that "not more than 12 cases of uterine rupture after the low Cæsarean have been reported up to date" (i.e., end of 1926) and believes that the performance of low section more generally, would reduce the incidence of uterine rupture to less than one-tenth of what it is.

Two objections to the lower uterine segment operation that I have found are:—(a) one cannot sterilize the patient and (b) preserving the uterus in a septic case may mean the death of the patient from puerperal sepsis after some time. It is my belief, therefore, that if the patient is frankly septic, (i.e., with a raised temperature and an offensive discharge) or in a doubtful case if she has had several children, or if she is suffering from osteomalacia, the wisest plan is to do a Cæsarean hysterectomy, which is what may be called Type 3. I have never regretted doing it. The technique is briefly as follows:—

III. CÆSAREAN HYSTERECTOMY.

Carefully sterilize the vagina. After opening the abdomen, very carefully pack off the area of the uterus which it is proposed to incise. Open the uterus as for the classical section and deliver the baby. (If the baby is known to be dead, it should be left in the uterus which should be delivered unopened outside the abdominal cavity.) Carefully pack towels behind and around the uterus which is now delivered outside the abdomen. Leave the placenta in the uterus or push it into the vagina. Subtotal hysterectomy should now be performed or total hysterectomy if the os is widely dilated. The peritoneal cavity can be drained if it is considered necessary either through the lower angle of the wound or through the vagina.

I am convinced, furthermore, that this operation should entirely displace those dreadful operations of embryotomy where, in a series of very long and difficult manipulations, the foetus is removed piecemeal through a contracted pelvis. The mortality of embryotomy is enormous and would be vastly diminished by substituting for it Cæsarean hysterectomy.

SEVEN CASES OF DIAPHYSIAL ACLASIS (MULTIPLE EXOSTOSIS) IN INDIANS, INCLUDING FOUR CASES FROM ONE FAMILY.

By H. STOTT, M.D., M.R.C.P., D.P.H.,
LIEUTENANT-COLONEL, I.M.S.,
Professor of Pathology and Physician,
and

RAGHUNANDAN LALL, M.B., B.S.,
Reader in Radiology, King George's Medical College,
Lucknow, India.

MULTIPLE exostosis (the diaphysial aclasis of Sir Arthur Keith) does not seem especially rare in Indians, but it appears that in all the London museums of pathology there is only one skeleton which illustrates this condition. Our attention

was first closely drawn to the disease by the admission into King George's Hospital of the patient whose history follows as Case 7. This patient died in hospital and we were fortunate in being able to obtain his skeleton for our museum. Plate I, fig. 1 shows the patient in life, Plate I, fig. 2 shows an X-ray photograph of his skeleton taken during life, and Plate I, fig. 3 his actual bones. A summary of what is known of the pathology of his condition follows the case description. Cases 1, 2, 3 and 4 are from a remarkable family of whom 9 were reported to be affected amongst 27 members. Case 5 was an old woman and case 6 a female child both without known family history.

Case No. 7.—The patient was a Hindu male of about 28 years, a Sadhu by caste and a non-vegetarian. He was admitted on 9th December, 1926, into King George's Hospital, Lucknow, for joint pains producing difficulty of movement during the past 2 months, also for breathless-

Skiagram 2.

ness, cough and slight fever for 6 months. He died in hospital on 12th January, 1927.

History.—His history was unreliable. He stated that the joints of the lower limbs and the right wrist had become swollen and painful after a dysentery attack two months previously. Before that he could walk and run like other men. He said he had had a penile sore and a penile discharge six months ago, that his father had had syphilis and that both parents died of

cholera. He stated that he had not noticed the bony enlargements round his joints. None of his near relations had bony projections round

Skiagram 2.
(Latest view.)

these joints. He lived in Bilaspur until he was 12 years of age, in Ajudhia until he was 14, and in Hardwar until he was 21. None of these are endemic goitrous areas. He had never had a goitre.

Condition on Admission.—Patient was thin and weak, weight 83 lbs. Height 5 ft. 3 inches. Chest (nipple level) 30 inches. Abdomen (umbilicus) 26 inches.

Locomotor System.—On examination the curious bony projections round both knee joints and ankle joints attracted immediate attention (*see photo. 1*). These projections gave the region of the knee joints an elongated appearance, and an apparent shortening and lateral curvature to both tibiae. On closer examination, irregular projections from the upper and lower extremities of the tibia, fibula and femur on both sides could be made out, but the main enlargements were round the knee joints, that is, at the region of maximum growth of the leg bones. One projection, on each side, in the region of the adductor tubercle was especially marked. In the upper arm the expansion of the bony extremities was less but was again at the ends where growth was greatest, i.e., at the shoulder and wrist joints. The carpal, tarsal, metacarpal, metatarsal and phalangeal bones

PLATE I.

Fig. 1.

Fig. 2.

Fig. 3.

were in the main unaffected, but one or two bony nodules could be felt at the base of the metacarpals and metatarsals.

The pelvis seemed unaffected except for an obvious nodular liping along the outer margin of each iliac crest. In the shoulder girdle a similar nodular liping existed along the vertebral border of the scapula and to a less degree along the scapular spine. The coracoid process was enlarged on both sides. The bony wall of the chest showed two marked changes. The left tenth rib was markedly expanded throughout its

marked degree of the right wrist—which was considered to be of a totally independent nature either post dysenteric or possibly tuberculous. No urethral pus could be expressed and no gonococci were detected in the prostatic secretion. An average of several total blood counts worked out at 8,080 white cells per c.mm. with a differential count of 65 per cent. polymorphonuclears, 32 per cent. lymphocytes, 2 per cent. large mononuclear, and 1 per cent. eosinophile cells.

Respiratory System.—Both lungs showed signs of diffuse broncho-pneumonia, and tubercle bacilli

Skiagram 1.

whole length, and there were nodules where the costal cartilages joined the bony ribs giving the appearance and feel of a rickety rosary. The hand and face bones were unaffected, so also was the spine except that the posterior process of the 7th cervical and 1st dorsal vertebræ seemed unduly prominent.

None of these bony growths, of themselves, limited the joint movements but there was some slight swelling of the right ankle and to a more

were present in the sputum. There were no dull areas. The temperature showed an evening rise to 99° or 100°. On only one occasion did it rise beyond, to 102°.

Alimentary System.—Normal, except that the spleen was enlarged to four fingers below the costal margin, and was very hard in consistence. The enlargement was probably malarial though no parasites were found in the peripheral circulation.

the tibia and fibula are often fused as in this case. Also growth of the distal end of the ulna is deficient, whilst that at the distal end of the radius continues—whence the radius becomes “bent to form a bow,” the ulna serving as a

They have never been painful nor tender. He cycles comfortably and well. The tumours gradually enlarged in proportion to his body growth and have not been growing lately. No venereal history. Lymph glands, thyroid and

Skiagram 5.

Skiagram 6.

“stretched string.” The proximal end of the radius is sometimes dislocated and the external epicondyle of the humerus detached.

Case No. 1.—Syed Jawad, a Madrasi male, aged 18 years, complained of bony growths around his knee, wrist, and shoulder, present since birth. These growths cause him no trouble.

spleen normal. All systems normal. Height 5 ft. 8 inches, chest at nipple level 30½ inches, weight 120 lbs.

Position of Bony Outgrowths.

(1) Around both knee joints especially at the lower ends of both femora, with marked pro-

jections $2\frac{1}{2}$ inches above the joint. Also expansion of upper end of both tibiae and fibulae (see Skiagram 1).

(2) At lower end of radius on the right side about 2 inches above the wrist (Skiagram 2

scapula shows marked thickening.

(5) The costo-chondral junction of the left sixth rib shows marked thickening, also less thickening at the right third costo-chondral junction.

Skiagram 7.

Skiagram 8.

shows both lateral and antero-posterior views).

(3) At the proximal end of left humerus, just below its head (Skiagram 3).

(4) The lower half of the left border of the

The iliac crests, spine, skull and face bones, also the tarsal, metatarsal, carpal and metacarpal and phalangeal bones and phalanges appear free. So also are the ankle, hip and elbow joints.

Case No. 2.—Syed Husaid, brother of case 1. A school boy, aged 12. Duration of enlargements, since birth. No inconvenience.

Sites of Noted Enlargements.

(1) *Around both knee joints.*—Lower ends of both femora are enlarged and bony projections also arise from them, mesially as well as laterally, the latter being more prominent. The biggest outgrowth is at the upper end of the right tibia, but both tibia and fibula are affected.

(2) *Above both wrist joints.*—Especially on volar surface of radius one inch above joints. The lower end of left radius is also enlarged and the epiphysis is deformed (*see* Skiagram 5).

(3) *Below head of left humerus.*—A small nodular growth.

(4) *Sterno-costal junctions of 5th and 6th ribs.*—Small bony nodules.

Case No. 3.—Sister of Case 1, aged 28.

Unmarried. We were ourselves unable to see this case and Case 4 owing to purdah. They were, however, examined by a lady student.

Position of Outgrowths.

(1) Dorsal surface of left radius, three inches above wrist.

(2) Seventh right rib, external surface, almond size, three inches from sternum.

(3) Right clavicle anterior surface, two inches from sternal end.

Case No. 4.—Sister of case 1, aged 14.

Position of Outgrowths.

(1) Dorsal surface of right radius, two inches above wrist, small.

(2) Left clavicle anterior surface, two inches from sternal end.

Family History of Above Four Cases.

There is a marked family history connecting the above two brothers and two sisters with their near relations. The brothers are two of 16 children, six of whom are known to be diseased. Of nine brothers four were affected and of seven sisters two were affected. There was one mother of these 16 children and both she and her family were healthy. Both the father and the grandfather of these children were affected.

							18 years.
							Syed Jawad (Case I above).
							17
							years.
							14
							years.

Skiagram 9.

In the father's family there were seven children, three males of whom two were affected, and four females none of whom were affected. There is no history of any other relations suffering from this trouble. The family state that a distant ancestor on his death-bed said that bony outgrowths would be a future characteristic of his family, and that this would be transmitted through his sons. The family tree is given on the previous page; diseased members are shown in squares.

Children Nos. 13 (Case 1), 16 (Case 2), 5 (Case 3) and 15 (Case 4) have already been described. There remain children 6 and 7. Child 6 is said to have bony outgrowths round both knees bigger even than those of case 1, but he can cycle without trouble. Child 7 has also big outgrowths round the knees. Possibly some of the children described as healthy have small outgrowths which would not be missed on medical and X-ray examination.

Case No. 5.—An old woman of 55 years, who came to hospital for gynaecological trouble. Large bony growths round both knee joints were noted (Skiagrams 6 and 7).

Case No. 6.—Sadika, a Mohammedan female child of 8 years, with hard lumps noticed at the age of one year on the left wrist and at the age of 7 round both knees. The wrist swelling was attributed to a fracture. All swellings have slowly increased in size but cause no discomfort. The patient is anæmic and thin but not emaciated. Height 2 ft. 11 inches. Weight 37 lbs. No evidence of congenital syphilis.

Family history.—Showed no similar condition amongst its members. Father and mother alive and healthy. Two brothers and one step brother, all healthy.

Position of Bony Lumps (Locomotor System).

1. *Shoulder joints*—upper ends of humerus on both sides are considerably thickened.

2. *Left scapula*—small nodule on vertebral border, just below spine.

3. *Both clavicles*—showed small nodules at acromial ends.

4. *Elbow joints*—small nodules on right olecranon process.

5. *Wrist joint*—big projection left radius—small ones of the right radius and both tibiae. (See Skiagram 9).

6. *Hip joint*—right great trochanter slightly thickened.

7. *Hip bone*—small nodules on both iliac crests.

8. *Knee joints*—bony thickening on all sides of both joints (Skiagram 8).

9. *Ankle joints*—some nodules both sides.

10. *Hands and feet*—normal.

11. *Ribs*—small nodules about one inch from costo-chondral junction on 5, 6, 7, 8, and 10th left ribs and on 4, 5, and 6th right ribs.

12. *Sternum, vertebræ, skull and face bones*—unaffected.

No abnormality was found in the respiratory, circulatory, alimentary, nervous, endocrine or urogenital systems.

A NEW TEST FOR ALBUMIN IN URINE.

By CHUNILAL BOSE, C.I.E., I.S.O., M.B., F.C.S.,
Rasayanachariya,

(Late Chemical Examiner to the Government of Bengal).

THERE is considerable difference of opinion among experts as to which of the many tests employed for the detection of albumin in urine should be regarded as the most reliable one. It is hoped that the addition of the following new test to the list will be appreciated by the medical profession on the ground of its simplicity, delicacy and reliability. When it is remembered that none of the recognised tests is without its fallacies and that certain special advantages are obtainable from the employment of the new test, the writer thinks that a case has been made out for its publication.

The reagent used for the new test is a saturated solution of saccharin in water prepared by boiling saccharin in distilled water until no more saccharin is dissolved. Allowing the solution to cool, the next step is to filter it and preserve the clear solution in a stoppered phial. On standing for some time, a few crystals of saccharin may separate out and settle at the bottom; these may be allowed to remain.

The test may be performed in the same way as one does the Heller's test with nitric acid. It is best to take a long and narrow test tube, about one-sixth full of clear urine and held in a slanting position. Now slowly and carefully allow the reagent to run along the side of the test tube by means of a pipette; it will settle at the bottom. If albumin is present in the urine even in traces, a sharply defined white ring will slowly form at the junction of the two layers of fluids, best seen when held against a dark background, the ring does not disappear on the application of heat. Strong nitric and picric acids behave in a similar way with albumin in the urine and with regard to delicacy, all the three tests are probably of equal merit, but there are certain advantages which the saturated solution of saccharin possesses over the other

tests and these are shown in the table below:—

and is not without risk so far as transport is concerned.

TABLE I.

Substances experimented upon.	REAGENTS USED.			
	Nitric acid (concentrated).	Acetic acid (ordinary).	Picric acid (saturated).	Saccharin solution (saturated).
Urine (nephritis)	Marked thick ring ..	No ring ..	Marked ring ..	Fine sharply defined white ring.
Urine containing mucin, and traces of albumin.	Two rings, one at the junction, the other at a higher level.	Cloudiness ..	A yellowish-white ring at the junction.	One sharply defined white ring at the junction.
Urine (hæmoglobinuria).	No ring at the junction; slight cloudiness at a higher level.	Slight haziness at the junction.	Marked ring at the junction.	A distinct sharply defined white ring slowly forms at the junction.
Urine containing slight excess of urea.	Heavy ring with crystalline deposit dissolved by heat.	Nil	Nil	Nil.
Urine containing slight excess of urates.	Diffused haziness ..	Nil	Nil	Nil.
Urine containing much excess of urates.	Thick cloud at the junction which nearly disappears on heating.	White precipitate	Yellowish-white precipitate.	A thin white ring at the junction, cleared on heating.
Blood plasma (very diluted).	Diffused cloudiness at the junction.	Nil	Large yellowish-white ring.	Distinct sharply defined whitish ring.
Peptone solution.*	Haziness at the junction	No cloudiness ..	Large yellowish-white thick precipitate not dissolved by heat.	Slight haziness at the junction.
Solution of egg albumin.	Distinct ring ..	Slight haziness	Distinct ring ..	Distinct ring.
Solution of urates (strong).	Copious white precipitate, disappears on heating.	Marked precipitate	Slight yellowish-white precipitate.	A whitish ring at the junction, dissolves on heating.
Solution of urea (strong).	Copious white crystalline precipitate, dissolves on heating.	Nil	Nil	Nil.

* Most probably the sample of peptone contained traces of albumin as an impurity.

It will be seen from the above table that the new reagent (saccharin) possesses certain advantages over nitric acid in that—

- (1) It does not precipitate mucin.
- (2) It does not precipitate urea.
- (3) It does not precipitate urates unless these are present in the urine in considerable excess.

Besides, nitric acid is a strong corrosive liquid with a suffocating odour, leaves yellow stains on the fingers and for the busy medical practitioner is most inconvenient and dangerous to carry.

The heat and acetic acid test is certainly a very reliable one for albumin, but the presence of mucin in the urine complicates its application: this is easily got over by the use of saccharin solution which does not precipitate mucin. Moreover, acetic acid is a very pungent-smelling and irritant liquid

Picric acid is no doubt a very delicate test for albumin, but it precipitates other things as well, such as peptones, etc., which saccharin does not. Besides, picric acid leaves yellow stains on the fingers which are not easily removed by washing.

A saturated solution of saccharin is a perfectly harmless substance. It has no colour, no smell, has no caustic action on the skin and is non-toxic. It may be carried (if the stopper is well secured, and, better, if put in a "dropping" bottle) even in one's pocket for ready use at the bed-side of the patient.

Saccharin is prepared from toluene which is obtained from coal-tar naphtha by fractional distillation. Its chemical formula is $C_6H_4 \begin{matrix} \diagup CO \\ \diagdown SO_2 \end{matrix} > NH$. It is a colourless crystalline substance, moderately soluble in water, possessing an intensely sweet taste and

is generally used as a substitute for sugar in the diet of diabetic patients. The composition of the compound it forms with albumin has not yet been worked out.

On a review of the literature on the subject, the writer has been unable to find anywhere the mention of *saccharin* as a reagent for testing albumin in urine.

The discovery of the new test was somewhat accidental, the attention of the writer having been first directed to the albumin-precipitating property of *saccharin*, while it was being used with milk as a sweetening agent.

The best thanks of the writer are due to Dr. J. P. Bose, M.B., F.C.S., Diabetes Research Scholar, School of Tropical Medicine, Calcutta, for permitting him to use the laboratory for conducting the experiments and to his assistants for help in the preparation of the reagents.

REPORT ON THE INVESTIGATION OF AN OUTBREAK OF EPIDEMIC DROPSY IN RANGOON IN THE YEAR 1924.

By K. R. DALAL, L.M.&S. (Bom.), D.T.M.,
D.P.H. (Liverpool).

Health Officer, Municipal Corporation of Rangoon.

THE following brief record of the observations made during the prevalence of an outbreak of epidemic dropsy in Rangoon in the year 1924 will be of interest to those studying the epidemiological aspects of the disease. So far as the city of Rangoon is concerned, this outbreak appears to be the first of its kind. My attention was first drawn to the prevalence of this disease by a correspondence that had appeared in one of the daily papers under the caption, "A new disease in Rangoon" in July 1924. A circular letter was addressed to all the medical practitioners and the hospital authorities drawing their attention to the incidence of cases of epidemic dropsy occurring in the town and requesting them to notify all cases that they might come across in their practice so as to enable me to carry out investigations into the cause and spread of the disease.

From personal enquiries made in the majority of the cases notified, I had come to the conclusion that these cases were evidently typical cases of what is usually described as epidemic dropsy in Bengal.

The total number of cases recorded during this outbreak was 174 of which 6 proved fatal giving a case mortality rate of 3.45 per cent. Of the cases reported, almost all the sufferers belonged to the Bengalee Hindu community except in two isolated instances where the sufferers were Upper India Hindus.

In the majority of instances, most of the adult members of the family had been attacked simultaneously one after another at very short intervals except in two cases where one member only of groups of ten and eight, respectively, living

and messing together had suffered from this disease. On further enquiry it was ultimately found that the affected individual in one case used to take his meals with his brother's family at Kamayut which is a small village outside the city limits, where the whole of his brother's family had been down with this disease. In the second instance, the patient was primarily living at Okkyin village before he came to town where he developed the disease, but it was later ascertained that of the ten people who were living with him at Okkyin, four had developed the disease there also.

General History.—Some cases were very mild in nature, some rather severe with cardiac dilatation, dyspnoea and great debility. Of the total number, six proved fatal. In the majority, the attack started with some form of gastrointestinal derangement marked by diarrhoea. In a few cases there was a history of passing blood. Febrile symptoms were mild with a daily small rise of temperature in the evenings. Pulse was rather rapid and the heart was found dilated in all cases of some severity. Urine was generally scanty with absence of albumen and sugar. There was complete absence of any nervous symptoms, knee-jerks being present but feeble in cases with marked oedema. The attack was usually ushered in with diarrhoea, soon followed by swelling of the legs and feet. Oedema generally affected the lower limbs as far as the hips. Only in a few cases, had dropsy extended to the upper regions of the body and face. There was no eruption of any kind beyond a general erythematous rash on the swollen parts. Sensations of heat, tingling or burning were felt in the swollen legs and feet. In the majority, anaemia and debility were marked symptoms. Dyspnoea was generally complained of. The onset of the disease was sudden and the incubation period appeared to be a short one. The following case of a servant newly employed in a household suffering from this disease is the only instance where the incubation period of this disease could be more or less definitely ascertained. The servant in this instance was engaged for the first time by the party after an outbreak of epidemic dropsy in his household, including his old servant who had to be sent to hospital. This newly engaged servant began to partake of the same food as had been cooked for the household and he developed symptoms of this disease for the first time exactly two weeks after his entry into this household.

The observations made during this epidemic reveal certain features of interest from the epidemiological point of view as given below.

(1) This outbreak of epidemic dropsy was the first of its kind in the city of Rangoon as far as records show.

(2) The outbreak was as sudden in its onset as in its subsidence. From the table giving a statement of the number of cases where a reliable history was obtained with their respective dates of attack, it will be seen that the outbreak started

in the first week of July 1924, reached its maximum in the third week of the same month and had practically come to an end by the middle of August.

(3) The incubation period as ascertained from the single case recorded above appears to be not longer than two weeks.

(4) Practically speaking this epidemic was confined entirely to the Bengalee community which forms a small part only of the Indian community of the population. The Census population of different communities in Rangoon is as follows:—

Christians	25,350
Hindus	125,626
Mohammedans	62,070
Buddhists	114,298
Other classes	18,161
Total			345,505

Not a single case of the disease occurred amongst the Burmese or the Indian Telugu communities who form the great bulk of the population and who use Burmese rice as their staple article of diet.

(5) There were any number of infants and children in the families who suffered from this disease, but not a single case was found amongst any infant or child taking milk diet only.

(6) The staple article of diet common to all the sufferers was rice which was, in every case except one, what is known as Calcutta par-boiled rice.

(7) The rice purchased was mostly confined to shops owned by Bengalee merchants dealing in Calcutta rice.

(8) The only other common article of diet on which suspicion was cast was mustard oil which was used by all the sufferers for cooking purposes. This oil too is mostly imported from Calcutta. It is likely that a mixture of this oil with some other seeds containing poisonous ingredients may have given rise to this outbreak.

(9) There was no question whatever of the cause being due to any vitamin or other food factor deficiency as the sufferers were in the majority of cases well-to-do people.

(10) The general impression left on the mind at the time of the investigation was that the disease was due to some common infection or chemical poison or toxin from a particular consignment of rice or mustard oil imported from Calcutta and when that particular consignment had been disposed of all those who happened to consume from that lot suffered from this disease. This is the only theory that would account for the sudden outbreak of the epidemic, spread over different parts of the town, its equally sudden end within six weeks of its onset and its confinement to the one particular community which had a special predilection for Calcutta rice and mustard oil as essential factors in their daily diet.

Samples of rice collected from the houses of the sufferers and from shops which where the patients had purchased their rice supply were sent to Colonel Acton, the Director of the School of Tropical Medicine, Calcutta, who has reported the results of his examination stating that most of the samples sent were found to contain highly diseased rice grains. A few samples of mustard oil were also subjected to analysis but with negative results.

Some of the particulars, where a reliable history was available, are summarised in the following tables.

A Mirror of Hospital Practice.

AN INTERESTING CASE.

By T. S. DAKSHINAMURTHI, L.M.S.,

Sub-assistant Surgeon, Alipuram Jail,

Bellary Cantonment, Bellary.

A WELL-BUILT convict Mopilla aged 45 years, sought admission into the jail hospital on 1st May, 1928, for the removal of two hard growths, one on the external aspect of either thigh at its lower end. The growths themselves were not painful but they interfered with the free movements of his legs, causing him pain and a certain degree of obstruction when he tried to assume a sitting posture from a standing one and *vice versa*. He noticed them as small nodules as early as the twelfth year of his age. He did not give any history of injury.

On examination, the man was noted to have pronounced genu valgum and flat feet. In the standing posture, a hard bony growth of a size and shape not unlike that of a patella could be seen and felt on the external aspect of each thigh 1 inch above the upper border of the patella and extending for about 2 inches along the outer margin of the quadriceps extensor. The growths were loose and so freely movable that they could be easily pushed under the quadriceps tendon and be distinctly felt on the inner side of the thigh. The right one was slightly bigger than the left.

The two bony growths were removed under chloroform by Dr. V. J. Lopez, I.M.D., the medical officer. Both the pieces were found enclosed in a thin sheath of connective tissue. They were loose, non-adherent and almost similar to an ordinary adult patella in size and shape. They showed several small pit-like depressions on their surfaces.

The chief interest in this case lies in its diagnosis which may be (1) traumatic myositis ossificans, (2) ossified chondromata, (3) cancellous osteomata (4) developmental anomaly, to wit, supernumerary patellæ. The following points are against myositis ossificans:—(a) Absence of history of any injury (b) complete absence of pain and stiffness in the muscles concerned (c) the symmetry of the growths.

In favour of developmental anomaly, to wit, supernumerary patellæ, there are:—

- (a) The size and shape of the growths.
- (b) Their situation close to the patellæ.
- (c) The symmetry.
- (d) Other congenital abnormalities, such as genu valgum and flat feet.

My respectful thanks are due to my Medical Officer, Lieut. M. R. W. Hart, M.B.E., M.R.C.S., I.R.C.P., I.M.D., who kindly permitted me to publish these notes.

POST-ENCEPHALITIC PARKINSONISM.

By FRANK NORONHA, M.B., C.M., D.P.M. (Eng.),
Superintendent, Mental Hospital, Bangalore.

THE term "extra-pyramidal" is applied to certain tracts in the central nervous system which conduct impulses downwards from the subcortical region of the brain. These tracts are normally under the control of the pyramidal system, and a functional combination of the two systems is necessary for normal voluntary activity. Any lesion in either of the systems leads, therefore, to a motor disturbance. A lesion in the pyramidal system in the neighbourhood of the internal capsule leads to post-hemiplegic rigidity and athetotic phenomena, due to unrestrained activity of the extra-pyramidal system.

But cases are met with where the signs referable to the extra-pyramidal system are found without any of the characteristic signs of a pyramidal lesion. These signs consist of disturbances of motility and those associated with changes in muscle tone, and are known as Parkinsonian, on account of their likeness to Parkinson's disease. These phenomena are also observed as a frequent sequela of epidemic encephalitis.

The following cases show the characteristic signs of an extra-pyramidal lesion in young adults and are probably post-encephalitic.

S., æt. 25, ryot, complains of stiffness of the body and inability to work. Duration of the disease is 3 years. It commenced with headache and excessive sleep for one year followed by tremors and stiffness of the body. He is physically well developed. Blood Wassermann test is negative and urine is healthy. Examination of the nervous system reveals a well marked hypertonicity of the whole body resulting in a bent attitude and fixity of expression (vide Fig. 1). Passive movements of the limbs are difficult and automatic associated movements are absent. Superficial and deep reflexes are normal and there are no pathological reflexes. Voluntary movements are slow and are interfered with by the rigidity and tremor. The tremors are in the extremities on both sides, in the upper eyelids and tongue and are increased on exertion. There is no sensory or vasomotor disturbance. The cerebro-spinal fluid shows increased pressure without any other pathological manifestation. There is no evidence of mental disorder.

The next case is similar, except that the signs are unilateral.

N., æt. 23, goldsmith by profession, has had the disease for 3 years. It commenced with fever for a month, followed by insomnia, mental dullness and general physical weakness. Then tremors of the left hand were noticed followed by tremors of other parts of the body. On examination, hypertonicity and tremor is found to be restricted to the trunk and extremities of the left side. Facial expression is maintained but

the left angle of the mouth is slightly drawn up. The rigidity of the left side is noticed in the "drawing up" of the left shoulder and knee as

Fig. 1.

Post-encephalitic Parkinsonism characterised by rigidity, fixity of expression and tremor (bilateral).

compared with the right side. (Vide Fig. 2). He loses his equilibrium on slight extension of the trunk and falls backwards. Blood examination gives a negative Wassermann reaction and the cerebro spinal fluid shows increased pressure.

Patients with similar manifestations are frequently met with and on inquiry into their histories we find that the trouble could be traced back for a long period, of 3 years and more. Some of the patients trace their trouble to the first influenza epidemic in 1918. The initial fever is likely to be mistaken for influenza or typhoid.

Unlike a typical case of epidemic encephalitis, the abovementioned cases are free from oculomotor or other cranial nerve palsy, but the initial fever, accompanied by headache and lethargy or insomnia would lead one to class them as post-encephalitic Parkinsonism with lesions in the extra-pyramidal system.

In England there has been a gradual increase in the number of cases recorded annually, since the disease was made notifiable in 1919, and it would be useful to determine the extent to which this disease is prevalent in India.

Fig. 2.

Post-encephalitic Parkinsonism. Unilateral (left side) rigidity and tremor.

A CASE OF AMYOTROPHIC LATERAL SCLEROSIS IN AN EAST INDIAN.

By V. C. RAMBO, M.D.,

*Mungeli Area Christian Hospital and Dispensaries,
Mungeli, Bilaspur District, C. P.*

DURING a recent tour among the villages, of which there are nine hundred within a radius of thirty miles of Mungeli, Central Provinces, the writer visited the Patheria branch dispensary. Here was brought to him a case with such outstanding features that the diagnosis could not be mistaken as being any other than amyotrophic lateral sclerosis. The reason for this recognition was the vivid memory of a very close personal friend who died with this sad and hopeless disease while the writer was an interne in Philadelphia. Never having seen such a case in an East Indian, the case is presented herewith.

REPORT OF CASE.

History.—A man Dukhalu by name, Patheria dispensary case No. 1571, 56 years of age, a Chamar by caste, from the village of Charbhatta, was brought to the dispensary with the complaint of, "Dribbling of saliva and inability to speak or swallow." The patient's wife and friends gave the history of the disease and the patient assented, nodding his trunk and head together when questioned; he could not nod his head unless he

moved his trunk also, and made signs with difficulty. Six months ago, they said, the patient was the strongest man in the village. He could go any distance with a load and lift almost prodigious weights with ease in spite of his age. At this time, without any premonitory symptoms, his voice began to fail and swallowing became difficult. Within a month, his voice, formerly strong, was gone and he could not swallow his food without pushing it back into his throat with his thumb. His tongue became "useless" and small. At this time, saliva began to dribble from his mouth and has flowed from his mouth ever since. This has caused itching of his face which has added to his discomfort. With the onset of these symptoms every muscle of the body began to twitch. This became a constant annoyance and though there has never been any pain this twitching has been the cause of restless nights and comfortless days. As the days passed, the patient and his friends noticed loss of weight and a wasting away of muscles and marked weakness until even the lifting of his head and sitting up has become a great effort. There have been no symptoms referable to the digestive system except that he is not able to eat enough. No symptoms referable to the other systems have taken a part in this picture. There has been no fever at any time before or during this illness.

The past medical history throws no light on the subject. The patient has always been well and strong. There is no history of any illness except smallpox in childhood. Venereal disease is denied. (In the villages there is no compunction to the frank statement of the history of venereal disease if it has been present.)

He has had four children who together with his wife are living and well. There is no history of such a disease in his family.

The social history is interesting. The patient is a poor peasant farmer. He has never been allowed by his caste to eat red spinach, brinjal, masur dal, fish or any food cooked in cast-metal dishes, only food cooked in beaten-metal vessels is allowed. He is not allowed to smoke or use tobacco in any form. Two years ago, his caste advanced into the Hindu group and putting on the sacred thread he added to the restrictions that already bound him that of doing without meat of any kind.

Physical Examination.—Patient is a big-boned, well-developed, well-built man of about fifty-five or sixty years of age. He sits on his haunches with his shoulders stooped, his head bowed, his mouth open as though it were impossible to close it, and from it thick viscid saliva flows almost in a constant stream. His face is thin and has a mask-like expression. His body is emaciated and his skin hangs loosely as though he had recently lost weight. The spines of the scapulæ are prominent, the muscles of the scapulæ sharing in the manifest atrophy of all the voluntary muscles of the body. Fibrillary twitching of all voluntary muscles is present. The

temperature, pulse and respirations are normal. The head, ears and nose present no abnormality. The right eye has a cataract. The left eye has an early cataract, but vision is still quite good. There is pallor of the conjunctivæ. The mouth is relaxed and wasted with weakness of the masseters. The gums are retracted but pyorrhœa is not marked and all the teeth are in a fair state of preservation. The tongue lies helplessly in the floor of the mouth fully 1.5 c.m. below the border of the lower teeth. The tongue cannot be protruded. Over the surface of the atrophied tongue, whose surface is thrown into folds, there are manifest multiple fibrillary contractions. These contractions present themselves in from four to a dozen places simultaneously. There is apparent atrophy of the pharyngeal muscles also, for the pharynx appears unusually large and roomy. The uvula cannot be raised. The neck and chest present no abnormality besides the muscular fibrillation and atrophy mentioned above. The heart has no murmurs or other adventitious sounds. At the time of the examination there were very few fibrillations present in the abdominal muscles. On speaking of this to the patient's wife she volunteered the information, that at times the fibrillation in this area was very marked.

The nervous system deserves special attention. All the coarser motor reflexes are definitely increased. The knee jerk, Achilles reflex, biceps, etc., are ++. There is marked weakness in all the muscles and all are easily fatigued. There is a slight rigidity of all muscles and they react sharply to percussion. The Babinski reaction is absent. No ankle clonus is present. The abdominal reflexes are absent. There is absolutely no sensory disturbance. The mind is clear and active. There is no tenderness manifest on ordinary pressure anywhere. There is no pain or aching, and no headache. The fibrillary twitches mentioned above, are marked in all except the abdominal muscles, where they are present, but only after close observation are they seen.

Diagnosis:—

- (1) Amyotrophic lateral sclerosis with early bulbar involvement.
- (2) Pyorrhœa.
- (3) Cataract.
- (4) Secondary anæmia.
- (5) Eczema from saliva dribbling over the cheek.

The diagnosis was made from the history of a progressive muscular atrophy with involvement of the bulb accompanied by fibrillation of the voluntary muscles, increased deep reflexes and paralysis, together with a lack of any sensory disturbance. No other disease gives this syndrome.

Prognosis.—There is constant danger from choking or from aspiration pneumonia. Even if one of these complications does not develop, respiratory paralysis, heart failure or starvation will not allow many more months of life.

Etiology.—This is not known. Exposure to damp and cold, various forms of poisoning, auto-intoxication and other causes have been mentioned. There is no proof that syphilis has any relationship to the disease. Did the atrophy in this case come from a sudden leaving off of all meat and eggs, the patient having partaken of a diet including such things for over fifty years?

Treatment.—This is empirical. There is no medicine that has any curative value. Considering the diet deficiency as a possible cause it would be illuminating to see what effect the new liver and vitamin treatment, given through a stomach tube, might have upon the disease. The completely degenerated cells could not be brought back to their function again, but the process might possibly be stopped. Neither the patient nor his family, however, can be prevailed upon to come where such a treatment might be given nor to break his caste bonds in order to take any such treatment.

Comments.—To the writer there are several features of interest in this case. In the first place he had never seen or heard of a case of the disease in an Indian. Another feature is the very rapid development of bulbar symptoms and the rapid progress of the disease. So rapid has been the extension that at the time of the examination the symptoms point to the fact that practically all the anterior and lateral pyramidal tracts including the sections in the spinal cord, medulla, pons, crus and possibly higher areas have become involved within the short space of six months. And, lastly, as mentioned above, there is the possible causative factor of a deficiency in diet at a time when the body was not able to make adjustments. This adjustment might possibly have been made had the patient been younger.

In these days we naturally refer all our unanswered queries to vitamin-deficiency for our answer.

NERVE ABSCESS IN LEPROSY.

By JOHN LOWE, M.B., Ch.B.,

Leper Hospital, Dichpali, Nizam's Govt. State Ry.

MUIR (1924) has recorded the occurrence of nerve abscess in leprosy. We have investigated this condition and our findings are as follows:—

Incidence.—In about 1,000 cases of leprosy of all kinds we have found nerve abscesses in 19 patients.

Nerves affected.—The commonest nerve to be affected is the ulnar nerve, 14 cases; the next commonest, the internal cutaneous nerve of the forearm, 3 cases; the median nerve, 1 case; the radial nerve, 1 case. We have never found a nerve abscess except in the arm.

The nature of the abscess varies somewhat according to the nerve affected:—

In the ulnar nerve.—In 8 cases there was a thickening of the nerve, sometimes very marked. In some cases the nerve was found as thick as

the little finger. The swelling usually affects the nerve for three or four inches above the elbow. When the nerve is exposed it is found adherent to the neighbouring tissues and when the nerve sheath is incised the abscess is found beneath the epineurium and between the nerve bundles. The abscess is sometimes localized to one place but at other times spreads up and down the nerve for a distance of two or three inches. Sometimes there may be two small abscesses an inch or two apart with a small sinus connecting the two.

The abscess usually contains white cheesy semi-solid matter. When examined microscopically, leucocytes, lymphocytes, and "lepra" cells are found. A few lepra bacilli are usually found, some in "lepra" cells and some lying free. These are usually short forms, only about 2 or 3 μ long, and may be degenerated or dead.

In six cases of abscess of the ulnar nerve a different condition was found. Here the nerve was not markedly thickened and in connection with the nerve, but slightly removed from it, there was found a swelling varying from the size of a pea to that of a pigeon's egg. This swelling was usually well defined and capsulated and not adherent to the skin, but in one or two cases the swelling was diffuse and had no definite margin and in one case the abscess was about to burst through the skin.

At operation these swellings were found to be abscesses containing cheesy matter as already described, enclosed in a fibrous tissue capsule and having a narrow neck with a sinus passing through the sheath of the nerve to the interior of the nerve. This condition had apparently been brought about by the formation of an abscess inside the nerve sheath, the abscess bursting outwards through the sheath forming an encapsulated swelling outside the nerve, instead of spreading up and down the nerve as in the other 8 cases. Hence the less marked swelling of the nerve itself.

In the radial nerve.—In one case a similar abscess was found outside the nerve.

In the internal cutaneous nerve of the forearm. other forms of nerve abscess were found in 3 cases. Here the abscesses have been small and in every case multiple. In one recent case five different abscesses quite small and with no apparent connections between them were found at intervals of about two inches along the nerve from elbow to wrist. This is exceptional. The two other cases have each shown two abscesses, in one case connected by a sinus running inside the sheath, in the other case separate. Some of the abscesses were confined inside the nerve sheath, some had burst out into the subcutaneous tissue.

The median nerve.—In one case a double abscess was found situated just above the elbow, both abscesses being inside the sheath and joined by a sinus.

Symptoms and signs of nerve abscess.—These are an exaggeration of the previously existing signs of nerve leprosy. In many cases there is

marked swelling of the nerve, extreme tenderness, severe neuritis, increase in anæsthesia, and contraction of fingers. These symptoms are most marked in those cases where the abscess is confined inside the nerve sheath as the pressure exerted by the abscess is severe. When the abscess bursts through the nerve sheath these symptoms are much less as the pressure is reduced.

Sometimes there is a definite fluctuating swelling but this is usually found only in those cases where the abscess is outside the nerve sheath.

Causes of nerve abscess.—The formation of the abscess often appears to be associated with the occurrence of leprosy reaction. A patient gets a nerve reaction and a swelling forms on the nerve, which diminishes when the reaction subsides but does not entirely disappear. A few weeks later another reaction occurs and the swelling increases, and with subsequent reactions an abscess is formed. It is noticeable that nerve abscess has been more frequent in those patients who are receiving potassium iodide-antimony treatment for leprosy. This is apparently due to leprosy reaction caused by this treatment.

It is also noticeable that nerve abscess is often associated with the milder form of the disease where the infection is slight and the patient's resistance is comparatively high. In three cases the disease was apparently confined to the one ulnar nerve and the only symptoms present were those due to this nerve involvement. In six cases there were more general nerve symptoms but no lepra bacilli were found apart from those found in the nerve abscess. In the other ten cases there were some slight signs of skin leprosy but the predominating lesions were nerve lesions. In our experience the formation of nerve abscess, though troublesome in itself, is associated with a high degree of resistance of the patient and so is not an unfavourable sign with regard to the disease.

Treatment of nerve abscess.—In every case where nerve abscess is suspected, the nerve should be exposed and the sheath incised. If an abscess is found it should be scraped out with care to avoid damage to the nerve tissue. Drainage after the operation we have found unnecessary except in one case where the abscess was large and about to burst through the skin.

On operation, whether an abscess is found or not, the nerve sheath should be incised over the whole area of thickening, the nerve should be freed from all pressure especially in the ulnar nerve between the olecranon and the internal condyle of the humerus. Operation in these cases relieves pain, which may be very severe, and undoubtedly often prevents the development of contraction of the fingers and trophic lesions.

Prevention of nerve abscess.—In cases receiving potassium iodide treatment, great care must be exercised in regulating the dosage so that only mild reactions are produced. If nerve reactions are severe they should be controlled by injections

of adrenalin subcutaneously and of 0.02 gram of potassium antimony tartrate intravenously.

Dr. Muir has recently suggested to us the oral administration of "Ephedrin" to control nerve reactions. In patients subject to nerve reactions this may be given at the same time as or shortly after the potassium iodide and the nerve reactions can thus be prevented or rendered much less severe.

AN INTERESTING CASE OF MELÆNA AND HÆMATEMESIS IN A NEWLY-BORN BABY.

By S. C. SEN GUPTA, L.M.F.,

Resident Medical Officer, Lakhpara Tea Estate, Banerhat P. O., Jalpaiguri District.

A HINDU girl, aged about 19 years (secundipara) was delivered of a male child on 4th December, 1927, at 7-30 p.m. Both the mother and the child were well on 5th December, 1927. But on 6th December, 1927, at about 9-30 a.m., when I was away on duty, I was informed by a maid-servant that the newly-born child was vomiting pure blood. I then hurried to the place and saw that the child was lying quietly on the mother's lap in a pool of blood. At this sight I was puzzled for a moment and could not ascertain its cause.

On examining the child I found the following state of affairs:—

Pulse	..	Fair.
Respiration	..	Normal.
Temperature	..	Normal.
Abdomen	..	Not markedly distended.
Cut end of the umbilical cord	..	Satisfactory.
Anus	..	Satisfactory.
Urinary meatus	seemed to be plugged with mucus.	

History of no passing of urine since birth and of muddy stool passed once or twice.

No other abnormality could be detected.

Previous History.—First issue was normal. The first child is still living in sound health.

Finding no other alternative I simply gave one drop of adrenalin chloride solution (1 in 1,000) with a teaspoonful of milk by mouth. The mother of the child gave that milk to the child in my presence but the child at once vomited it out with about 1½ ozs. of blood, the colour of which was bright red. There was no clot of blood with the vomit but all along it was liquid blood and a little thick. The family did not like my giving an injection to such a young child. At 11 a.m. on the same day the child passed a dark red semi-liquid stool, quantity about one ounce.

I then informed one of my colleagues and he came but was unable to suggest any other line of treatment. He simply passed a sterilized needle through the urinary meatus to see whether

whereas in the present Bill each province sends one member elected by private practitioners, so that their representatives will constitute about one-third of the whole council. Much will depend on whether the profession elect teachers or politicians to represent them. Time alone will show how this privilege will be used. The electorate is restricted to those holding university qualifications.

The powers of the Council cover:—(1) the determination of the qualifications and conditions necessary for registration on the register for British India including scrutiny and approval of the course of study, (2) the employment and maintenance of medical inspectors and (3) the arranging and bringing into effect of any schemes of reciprocity with any British, colonial or foreign medical licensing body or authority. The main agency for determining the qualifications necessary for registration on the All-India register will be the medical inspectors. While the courses and curricula of universities will be subject to scrutiny in order to ensure that they are calculated to provide a satisfactory standard of proficiency in medicine and surgery, there will be no attempt to prescribe these. The initiative in this matter will as at present rest with the educational authorities directly concerned. Registration on the council's register will carry certain privileges, failure to secure such registration will impose certain disabilities.

It will be noted that no reference is made to the class known as licentiates. The Government of India are of opinion that the attainment of uniformity in standards should in the first instance be attempted only in relation to those who possess graduate qualifications. The Government of India hold the view that the standards of education and qualifications of medical licentiates should be levelled up throughout India; but that for the present provincial needs and conditions may render the immediate realisation of this ideal impracticable. A second gap in the Bill is the absence of any provision to define the relations of the central with provincial medical councils. The main functions and powers of provincial councils are:—

- (1) To supervise and maintain the provincial register;
- (2) To require particulars of their examinations from institutions included in or desirous of being included in the schedule to the provincial acts constituting the council and to demand that a member of the council deputed for the purpose shall be permitted to be present at any examination; and
- (3) To refuse to register or direct the removal from the register of certain classes of persons.

If the view that the proposed All-India Council should first concern itself with graduates is accepted, provincial councils will retain and exer-

cise all these powers in regard to licentiates. Functions (1) and (2) will, in respect of graduates, pass to the central council. Function (3) which relates to disciplinary power will, with reference to persons whose names are borne on the All-India register, also pass to the central council. The conditions for disqualification will be regulated by rules framed by the central council instead of by those laid down by the provincial acts. It would seem more convenient that disciplinary action should, in the first instance, be taken by provincial branches of the central council, appeals being heard by the latter or by a sub-committee of it. Minor changes in the provincial acts may be required to regulate the relations between the proposed central and existing provincial councils and to link those latter with the central council.

The necessity for an All-India Medical Council has long been apparent and the recent strained relations between the University of Calcutta and the General Medical Council of recent years have rendered the problem acute, by reason of the hardship inflicted on students desirous of prosecuting their studies in the United Kingdom. It is difficult to see any reasonable grounds on which objection can be taken to the objects of the Bill.

The report of the Committee of the Bengal Medical Association deals only with minor points arising mainly from failure to appreciate the main provision of the Bill, which is that it deals with graduates only and not with licentiates nor with practitioners of the indigenous systems of medicine. It is not proposed to supersede the provincial councils so far as licentiates are concerned, nor to tackle the difficult problem of standardising the examinations for the licentiate-ship of the different provincial medical faculties. We are inclined to think that this problem will eventually settle itself by the gradual approximation of the licentiate standard to that of the graduate, until the former merges into the latter and a uniform standard of qualification for all medical practitioners throughout India is attained. The present position should be looked on as a temporary expedient to meet the urgent need for medical aid in the rural areas of India and as merely a phase in medical education. The state of affairs in Great Britain fifty years ago was not so very different, with the "Hall," the "College" and the Universities representing three different standards of qualification and with the almost universal employment of unqualified assistants to treat the less important cases. The suspicious member of the Bengal Medical Association's Committee who sees in the phrase *British Indian Medical Register* an attempt on the part of the Government to throttle those who practise the indigenous systems of medicine should study Section 1, Sub-section 2 of the Bill, from which he will learn that the expression "British India" is merely a geographical term. No one questions the right of the Universities in India to determine the courses of study and to

confer degrees, it is only when it comes to the right of the possessors of those degrees to practise medicine in any administrative area or country that the State steps in and claims the power to decide whether those degrees constitute a sufficient qualification. That this power should be exercised by provincial councils for licentiates, whose diploma is valid in India only and by a central council for graduates, who may thereby acquire recognition in countries outside India, is an equitable arrangement which we hope will be passed into law as soon as possible.

Nasal Obstruction.

By PHILIP A. HARRY, M.D., D.P.H.

(*The Prescriber*, July, 1928, p. 229.)

Infants and Young Children.—All are agreed on the evil effects of insufficient nasal breathing, and the symptoms that arise, nasal, aural, and general, are well known. It is, however, not generally accepted that the structural changes leading to the production of the adenoid facies are due to nasal obstruction in early infancy. In the second dentition it is found that the nose and naso-pharynx have failed to undergo their full normal development. The upper jaw becomes narrow and pointed, the face is pinched, and the teeth are crowded, the incisors protruding and the bite open. This is the typical "rodent face,"—the English face of continental caricaturists. Other signs of secondary importance are the narrow slit-like nostrils; and the disappearance of the natural grooves and depressions between the nose, cheek, and upper lip. The nasal cavities also show irregularity in development; the septum which should be smooth and vertical becomes crumpled and grows unequally while the palate is deformed and becomes high-arched. Deformities in the chest-wall are also noticeable, the sides of the chest being flattened and the sternum projecting so as to produce the condition known as "pigeon breast." In other cases a shallow depression forms round the ribs and sternum corresponding to the insertion of the diaphragm. The skeletal changes in the face are due to the direct mechanical effect of the naso-pharyngeal obstruction, while those in the chest-wall are produced by the constant sucking-in efforts made during inspiration by the thoracic muscles in their attempt to overcome the obstruction within the nasal cavities. The persistence of defective nasal respiration will also produce the evil effects of confirmed mouth-breathing, such as loss of the natural resonance of the voice, which becomes dull and toneless. Snoring is persistent and loud, and the breathing is heavy even during the day. The sense of smell is impaired and the appreciation of flavour is not keen. By tilting up the tip of the nose the mucosa of each side can be compared; it will be usually pale, oedematous, sodden, and covered with an abnormal amount of mucus.

In young infants other causes of nasal obstruction, such as congenital occlusion of the nostrils, anterior and posterior, congenital syphilis, and mongolism, will produce the general symptoms but not the typical adenoid facies, which is caused by the mechanical effect of the naso-pharyngeal growth. The only cure for the latter condition is the complete removal of the obstruction; the lay opinion that an infant can be too young for operation or that the tender age of the child prohibits surgical interference must be exploded,—postponing the procedure will increase the facial deformity and render remote the chances of the child's proper growth.

In young infants the symptoms are inability to suckle properly; as soon as the mouth closes on the nipple the difficulty of breathing is apparent and the child has to

let go in order to breathe. He also swallows air while trying to feed, this causes sickness and attacks of "wind"; indeed a frequent cause of flatulence in infants is enlargement of the naso-pharyngeal tonsil. This renders them more liable to digestive troubles and malnutrition. Nervous symptoms are more manifest, for example, laryngeal spasms, laryngismus stridulus, and various forms of suffocative attacks. Night-sweats, persistent cough, and other reflex symptoms are also noticed at this early period. Convulsions occur occasionally.

In these early months of the infant's life the post-nasal space is too small to allow of digital examination, and diagnosis must be made from the character of the obstruction and the history. The ordinary small-sized curette cannot be satisfactorily used, a small pair of adenoid scissors is more helpful, bearing in mind the fact that the posterior edge of the septum is more oblique than in the older child and that there is greater danger of injuring it.

Breast-fed infants are less liable to the development of adenoids than the bottle-fed. In congenital syphilitics a discharge from the nose is present in the majority of cases before the operation and is liable to persist even after the removal of the adenoids; it however, responds to suitable medical treatment.

The prevention of nasal obstruction in young children is important and can be achieved only by careful management. At this early age the mucous membrane of the nose and naso-pharynx is particularly susceptible to infection and the local resistance is very low. These infants should be protected from coming in contact with carriers of infection. The importance of breast-feeding cannot be over-emphasized.

Young Adults.—In young adults a disease of the nose that is occasionally met with is ozæna. The chief symptom of this complaint is nasal obstruction. The sensibility of the nasal mucous membrane is altered so that the normal sensation of air passing in and out of the nose is not felt; the presence of discharge and crusts in the nasal passages, together with the difficulty of blowing the nose, tends to foster the belief that the nose is blocked, although the passages are wider than normal. The diagnosis is rendered easy by the characteristic odour; there is no necrosis of bone, although an undoubted osseous atrophy exists.

Middle Life.—Nasal obstruction in middle life is due in the majority of cases to polypi, an inflammatory growth from the upper part of the nasal cavity. They are usually multiple, vary in size, and occur in both sides of the nose. The inferior turbinate bone is hardly ever the seat of polypus formation. The inflammation commences in the mucous membrane and extends to the underlying periosteum and bone. Any irritative condition of the mucous membrane of the nose or of the accessory sinuses will give rise to polypi; they are occasionally found in the frontal and sphenoidal sinuses and antrum. The diagnosis of the disease is not without difficulty; hypertrophy of the anterior ends of the inferior turbinates and septal deviations may be mistaken for polypi, but examination by transillumination and radiography will assist in making a decision.

The growth should be removed as close to its base as possible and any sinus disease treated afterwards. This is important, as a polypus may mask malignant disease of the nose, and it is only after removal that the firm, rough, bleeding and ulcerated surface of an epithelioma, or the soft friable mass of a sarcoma, can be discovered. Frequent attacks of epistaxis or repeated blood-staining of the nasal secretion should arouse suspicion of malignancy.

A polypus in the post-nasal space must be distinguished from enlargement of the posterior ends of the inferior turbinates, from adenoids, and from various forms of new growth springing from the vault or protruding from the posterior choanae. Examination of the post-nasal space with the rhinoscopic mirror will settle any doubt in the diagnosis.

The prognosis of nasal polypi is not satisfactory, if left untreated they show no tendency to disappear, but rather increase in size and lead to complications such as various lung conditions, chronic bronchitis, asthma,

middle-ear disease, impairment of the general health, and inflammation of the underlying bone extending into the sinuses. Even after removal of the polypi the source of the disease is not removed, the rarefying osteitis of the underlying bone continues, and fresh inflammatory œdema of the mucous membrane results, leading to recurrences. It is therefore essential, besides removing the polypus as close to its base as possible, that the affected bone should be curetted.

The prognosis is best in the case of solitary polypi, without sinus suppuration and of slow growth, and worst in the case of quickly growing polypi in the presence of sinus suppuration. In the former—due in the majority of cases to non-purulent nasal catarrh—simple removal by the snare without curetting will be sufficient to effect a cure; in any case it is inadvisable to curette until all the polypi have been removed by snare or forceps. By means of the curette the diseased and broken-up ethmoidal cells are scraped away. The bleeding is usually very profuse and preparation must be made for it. If possible, the patient should be prepared before the operation by the administration of some substance that will increase the coagulability of the blood. Packing the nasal cavity after operation is not desirable as it increases the liability to sepsis. Adrenalin solution should be used very sparingly as severe reactionary hæmorrhage is likely to set in afterwards. The after-treatment is important, especially in the cases with muco-purulent discharge, the nose being syringed daily with normal saline. If the discharge continues, painting the affected area with a 10 per cent. solution of nitrate of mercury ointment in liquid paraffin will prove satisfactory and will prevent the spread of the sepsis backwards to the pharynx and tonsil. Small granulations occasionally appear on the surface of the ethmoid bone several days after the operation; these are best treated by the application of chemical caustics such as a bead of silver nitrate or chromic acid fused on the end of a probe; these caustics should not, however, be applied to tags of mucous membrane or polypoidal remains owing to the inflammatory reaction that is likely to ensue.

The Bromsulphalein Test of Liver Function.

By ERNEST BULMER, M.D., M.R.C.P. (Edin.),

M.R.C.P. (Lond.).

(*The Lancet*, August, 1928, p. 235.)

BROMSULPHALEIN or phenoltetrabromphthalein sodium sulphonate was prepared by White; it is a whitish powder very freely soluble in water, and it can be given with impunity by intravenous injection in a concentrated solution. It is non-irritant, and in ordinary doses absolutely non-toxic. Normally the dye is seized by the liver, and the majority is excreted in the bile, traces only appearing in the urine. The rate of disappearance of the dye from the blood serum is important—after five minutes 20–50 per cent. remains in the blood, whilst at the end of half an hour there is none at all or a mere trace. It was argued that if the liver were damaged it would remove the dye with less rapidity from the blood after injection, and that the degree of retention of dye in the blood stream would give an indication of the degree of liver damage; the originators of the test, Rosenthal and White, denied that it had any dependence upon biliary permeability.

Technique.—The patient is weighed and the dosage is calculated on a basis of 2 mg. of the dye per kilo body-weight—the body-weight of the patient in pounds divided by 55 will give the exact quantity in cubic centimetres of the 5 per cent. solution employed. It is injected slowly into one of the arm veins. Thirty minutes after the injection, a sample of blood is withdrawn, preferably from the opposite arm, and in cases of early liver disease it may be necessary to take a sample after five minutes. After the blood has coagulated it is centrifugalised and the clear serum is pipetted into two small test-tubes. To one of these is added one or two drops of a 10 per cent. solution of sodium hydroxide to bring out the colour of the dye, and to the other tube a drop of 5 per cent. hydrochloric acid to clear the serum of any

hæmolysis. The amount of dye in the serum is now estimated by direct comparison with a series of standards, using a simple comparator box in the usual way. The standards may be prepared by adding 4 mg. of the dye to 100 c.cm. of water that has been alkalinised with 0.25 c.cm. of a 10 per cent. solution of sodium hydroxide. This represents the 100 per cent. standard, and a series is prepared ranging from 5 per cent. upwards by dilution with alkaline water. In practice it is much simpler to employ the series of non-fading standards prepared by Hynson, Westcott, and Dunning. The 100 per cent. standard represents the amount of the dye that would be present in the blood stream if none were removed; it is thus an arbitrary standard calculated on blood volume.

Clinical Findings.—(Rosenthal and White).

	Cases.	Retention expressed in percentages after 30 minutes.
<i>Non-liver</i> ..	25	0 or a mere trace.
Obstructive jaundice ..	5	97, 96, 90, 35, 30.
Cancer of liver ..	2	99, 20.
Catarrhal jaundice ..	3	75, 50, 35.
Arsphenamine jaundice ..	2	47, 22 (after 15 min.)
Biliary cirrhosis ..	1	45.
Portal cirrhosis ..	3	?, 22, 17.
Syphilitic cirrhosis ..	1	3.
Pre-eclamptic toxæmia ..	1	30.
Acute cholecystitis ..	1	10.
Chronic cholecystitis ..	1	5.

From experience with his own cases the writer arrived at the following conclusions:—

(1) Normal cases and those without any liver lesion showed a retention of 5 per cent. to a mere trace or even no dye at all.

(2) Cases of liver disease showed a retention which probably represented fairly accurately the degree of liver damage or functional impairment; 100 per cent. retention means that no dye is removed from the blood, and a retention of, say, 50 per cent. would mean that the liver was 50 per cent. incompetent, and so on.

(3) The test is one of liver function and not of biliary permeability; this is proved by the fact that many of the cases of complete obstructive jaundice did not give a 100 per cent. retention.

(4) The test is safe, simple, and it appears to be the best one we have.

A Note on Blood Changes Associated with Liver Diet in Young Convalescents.

By K. SHIRLEY SMITH, M.B., M.R.C.P. (Lond.)

and

L. E. H. WHITBY, M.D. (Camb.), M.R.C.P. (Lond.)

(*The Lancet*, August 11th, 1928, p. 277.)

IN order to find out whether the blood changes obtained with liver diet in cases of pernicious anæmia were confined only to that disease, it has been thought worth while to study the blood changes produced by the same diet in hospital patients free from any blood disease. Whereas the original work of Whipple indicated that liver diet was likely to be useful in all forms of anæmia, the first recorded results with liver diet in pernicious anæmia suggested that it was most specific for pernicious anæmia and exerted its maximum effect only in that disease. Recently it has been found by Vaughan and others that some cases of secondary anæmia respond to liver treatment, and we have found that relatively normal children show a transient, but definite stimulatory response to liver feeding.

The 11 cases selected for treatment in this investigation were between the ages of 3 and 15 years with the single exception of one girl aged 19. The majority of the patients were in surgical wards and were, during the experimental period, convalescing from such surgical conditions as inguinal hernia, tuberculous adenitis, and submaxillary abscess; others were in medical wards under treatment for such diseases as mediastinal adenitis

and oxaluria. On account of the special interest attaching to the blood changes observed in them, two cases are included in which the lymphatic system seemed principally affected; these were cases diagnosed as Hodgkin's disease and glandular fever.

Fresh cooked liver was given daily, the amount varying with the age of the patient; the older patients received 3 oz. daily and the younger ones 2 oz. A blood examination was made in every case before starting the diet and the feeding was continued for periods, varying between six and forty days. In the first few cases examinations were made at intervals of three or four days for a period of three weeks, but experience showed that the maximum effect was noticeable after about six days and that it declined thereafter. In no case were hæmatinic drugs given during the time of liver feeding.

Such observations as were made on the red cells and hæmoglobin show that these tended to increase. A leucocytosis was produced in seven out of the 11 cases. In seven cases also there was an increase in the relative and absolute number of polymorphonuclears. Neither the increase in the total leucocytes nor the increase in polymorphonuclears was maintained for longer than ten days. Lymphocytes showed a relative but not absolute reduction in nearly all cases. A definite absolute increase in eosinophils was produced in all instances, the striking figure of 61 per cent. being found in the case of Hodgkin's disease. An increase in granular or bone-marrow cells was also the rule. These results show that the administration of liver to patients who suffer neither from pernicious anaemia nor any other blood disease produces alterations in the blood comparable to those occurring in the treatment of pernicious anaemia. An interesting feature of the series is the eosinophilia which has been also found in pernicious anaemia by one of us and in secondary anaemia. The definite increase in the red cells and bone-marrow leucocytes shows that liver must exert a stimulating action on the bone-marrow. It is difficult to believe that stimulation is the only action in pernicious anaemia though evidently it is one essential feature.

We are inclined to suggest that liver is rich in a substance essential for the proper functioning of the bone-marrow; in pernicious anaemia, this substance, whatever it may be, is not absorbed in sufficient quantity from an ordinary mixed diet, perhaps on account of the achlorhydria, though it is possible to assimilate enough with massive liver feeding.

(These observations add support to the suggestions in the editorial note in the September number of this journal, namely, that this treatment should be given an extended trial in this country.—EDITOR, I. M. G.).

The Problem of Mount Everest.

(From the *British Med. Journ.*, August, 1928, p. 347.)

THE news that an eminent British physiologist has, this summer, blazed a new and unsuspected trail to the summit of Mont Blanc reminds us that mountaineering is, historically, a pursuit of scientific men. In the eighteenth and nineteenth centuries mountain climbing was undertaken almost exclusively by men whose interest was to observe the effects upon themselves of exposure to low barometric pressures. Within more recent years climbing has become a sport attracting men of divers callings, but such names as Hingston, Wollaston, Longstaff, and Somervell remind us that there are still to be found medical men fit and ready to share in the most hazardous expeditions to high altitudes.

These names, and with them the epic stories of those supreme adventures in mountaineering the several Everest expeditions, are brought to mind by a recent contribution to the *Lancet** on the physiological "Problem of Mount Everest," by Dr. Argyll Campbell. By general consent, the physiological limitation to the attainment of great height resides in the limit of man's adaptability to environments of abnormally low partial pressures of oxygen. At the top of Mount Everest the tension of oxygen is only about 7.5 per cent. of an atmosphere, being but a third of that at sea-level. What are the

physiological effects of low tensions of oxygen? To answer this question the physiologist has taken his laboratory to the mountain. He has also sought to bring the mountain into his laboratory. Closed chambers have been devised in which the subject of experiment is placed and in which the composition of the atmosphere may be controlled at will. Here may be studied the physiological and psychological effects of exposure to any desired oxygen tension under all manner of conditions of rest and activity. Many such studies have been made on man, and this "armchair mountaineering" has not been without its thrills. But the simulation of such extremes of atmosphere as those obtaining at the summit of Everest are not feasible with man, and Dr. Campbell's observations on animals are of special interest on this account. He has made prolonged studies of the effects upon a variety of animals—mice, rats, rabbits, guinea-pigs, cats, and a monkey—of lengthy sojourn in the decompression chamber. The animals were subjected to a gradual reduction of oxygen tension spreading over several weeks until a partial pressure of 7.5 per cent. of an atmosphere was attained. The rabbits, rats, and mice alone survived, and even amongst these groups there were casualties. The most notable pathological change observed was an extreme congestion of the liver and parts of the heart and lungs. This congestion must be attributed to failure in the forward movement of the blood for which the heart is held primarily responsible, though failure of the vasomotor nervous centres or other factors controlling capillary dilatation may be contributory. Dr. Campbell concludes that the ability to withstand low tensions of oxygen is conditioned by the ability of the heart muscle to maintain an efficient circulation under the abnormal conditions.

What, then, is the contribution of these experiments to the "problem of Mount Everest"? In the first place it is argued that the permanent effects of high altitudes are gradually established as the result of prolonged exposure to lack of oxygen. It, therefore, seems plausible that the daily inhalation of oxygen for several hours when at the base camps would be preferable to the policy of reserving the oxygen supply for use during the actual climbing at greater heights. It is further suggested that daily subjection to low tensions of oxygen in the decompression chamber might prove to be of valuable assistance in the selection and training of suitable climbers.

The experimental animals of Dr. Campbell were not required to undertake arduous exercise, and were not subjected to low temperatures, snow, ice, and chilling winds. Is it to be wondered at that his results give the author no confident grounds for the faith that man will conquer Everest and return? Yet such is the heart of man that we doubt if he will take "No" for an answer. Indeed, when we recall how near—how tragically near—to success were Irvine and Mallory and how Norton and Somervell reached 28,000 feet and came back, it is difficult to believe that the little more is beyond human reach.

Observations on Ultra-Violet Ray Therapy.†

By E. P. CUMBERBATCH, B.M. (Oxon.),
D.M.R.E. (Camb.), M.R.C.P.

(*The British Med. Journ.*, July 14, 1928, p. 43.)

THE first fact to recall is that ultra-violet rays are not all of the same kind. They differ in their wave-length, and they do not all possess the same biological, chemical or physical properties. Those with the shortest wave-length I shall designate by the number 20, and those with the longest wave-length by 39.‡ There are

‡ Abstract of a British Medical Association Lecture delivered to the Southport Division, March 30th, 1928.

† These numbers, when multiplied by ten, give the actual wave-length in millionths of a millimetre; when multiplied by one hundred they give the wave-lengths in what are known as Angström units. The shorter figures are less confusing for lecture purposes. The expressions "short," "medium," and "long," when applied to the rays, refer to their wave-length.

* July 14th, 1928, p. 84.

rays of every wave-length between 20 and 39. Rays with wave-length shorter than 20 do not concern us, because they do not reach the body. Those with wave-length of 40 are the *visible* violet light rays. The *visible* red light rays have a wave-length of 79. Rays with wave-length of 80 and over are the radiant heat waves, sometimes called the infra-red rays. I mention these facts because the ultra-violet lamps also emit these other rays as well as the ultra-violet, and the former possess therapeutic properties too. So when the practitioner exposes his patients to the ultra-violet lamp he administers phototherapy and thermotherapy as well as ultra-violet therapy. This is especially the case when certain types of lamp are used.

When these different rays fall upon the body they penetrate for certain distances, and then they are absorbed. Rays possess energy, and this energy is not lost when the rays are stopped. Either heat is produced or chemical changes occur, depending on the wave-length of the rays and the kind of tissue in which the rays are absorbed. The tissues react to these thermal and chemical changes, and various biological effects ensue. These effects, whether physiological, pathological, or therapeutic, are the outcome of the thermal or chemical changes caused by the rays.

Before we study these effects I must say a few words on the distance to which the different rays penetrate before they are stopped. This is important, because various kinds of tissue lie in the path of the rays, and the distance reached by the latter is dependent on the nature of the tissue as well as on the wave-length of the rays. Ultra-violet rays with wave-length from 20 to 24 are stopped in the stratum corneum of the epidermis. Those with wave-length from 25 to 33 pass through this layer, but are stopped in the stratum mucosum of the epidermis—that is, in the living epidermal cells. Those with wave-length from 34 to 39 pass through the entire epidermis, but are stopped by the blood in the sub-epidermal capillaries. Rays with wave-length of 40 (these are the *visible* violet light rays) probably do not penetrate further than the longest ultra-violet rays. On the other hand, the *visible* red rays (wave-length 79) have a much greater penetrating power; some of them reach the superficial strata of the muscles under the deep fascia before they are stopped. The *visible* green and yellow rays have an intermediate penetrating power. The invisible heat rays have a feeble penetrating power. It is doubtful whether those with the shortest wave-length (80) penetrate much deeper than the sub-epidermal capillaries, while those with longer wave-lengths do not penetrate as far.

We may now study the action of the various rays on the tissues which absorb them. As I have already said, the rays expend their energy in the production of thermal or chemical changes; their action ends there. The infra-red rays heat the tissues that absorb them. Since their penetrating power is very slight the distribution of the heat is superficial. The maximum temperature is produced on the surface; below the surface the temperature rapidly drops to normal. The *visible* light rays also expend their energy in the production of heat. By reason of the greater penetrating power of most of these rays they can heat to a greater depth than the infra-red rays. By means of the *visible* red rays it is possible to elevate the temperature of the superficial layers of muscle under the deep fascia. The ultra-violet rays with the longest wave-lengths (34 to 39) expend their energy in heating the blood in the sub-epidermal capillaries. They have no action, so far as is known, on the epidermis. These are the so-called "long" ultra-violet rays.

The rays which pass through the stratum corneum but are stopped by the cells of the stratum mucosum (25 to 33) produce *chemical* changes in these cells. These changes are of a destructive nature, and they kill the cells if the rays are sufficiently intense or are applied for a sufficiently long time. The dead cells are cast off by the process of desquamation. The separation of the remains of dead cells is, of course, a natural process, but in physiological states the cells that are cast off have died of old age. The artificial destruction of epidermal cells by ultra-violet rays is followed by certain biological

effects. They will be described presently. These rays are sometimes called the "medium length" rays. The rays with wave-length from 20 to 24 (the "short" rays) do not pass beyond the horny layer of the epidermis. Since this layer is composed of dead tissue the rays cannot produce any biological effect in it. If they fell on living tissue they would destroy it, but only to a very slight depth, because their penetrating power is so little. These very short rays can also kill bacteria; but to kill them they must reach the bacteria and not be stopped by overlying tissue. Unfortunately the rays which are most powerfully bactericidal (23 to 24) have a very feeble penetrating power. As the wave-length gets longer the germ-destroying power falls rapidly. Consequently we cannot expect ultra-violet rays to destroy bacteria (that is, by *direct* action) if they lie more than the very slightest depth below the surface.

There is another important chemical change which the rays bring about. This is what is known as the "activation of cholesterol." This substance is present in all growing tissues, and it plays an important part in metabolism. It cannot perform its function unless it is rendered active. Ultra-violet rays possess this activating power. In this way the curative action of the rays in rickets is explained.

Let us now consider the biological effects which follow the physical and chemical changes brought about by the different rays. The invisible heat rays and the *visible* light rays are thermogenetic. Consequently the biological effects of these rays are those of heat. The effects of heat are far-reaching, but the time at my disposal does not allow me to go into the matter. I might mention, however, that heat increases the action of those ultra-violet rays which bring about chemical effects.

It is believed that the ultra-violet rays with the longest wave-lengths (34 to 39) have no chemical action on the tissues. It is probable that they are thermogenetic. Their biological effects are therefore those of heat. The chemical changes induced in the living epidermal cells by the rays of shorter wave-length are not immediately followed by any *visible* effect; but after an interval of two to ten hours there develops an erythema. It lasts from a few hours to a few days, according to the length of exposure and the intensity of the rays. It then fades away. Desquamation begins after four or five days. The degree of erythema and the amount of the desquamation also depend on the length of exposure and the intensity of the rays—that is, on the dosage. With small doses the erythema is slight and the desquamation is indiscernible. With less small dosage the erythema is more evident and the desquamation is apparent. With heavy dosage the erythema is intense and blisters may form. After a few exposures sufficient to procure a fair degree of erythema there develops in many subjects a pigmentation of the skin. This is due to the formation of a substance known as "melanin" in the basal cells of the epidermis. The most potent erythema-producing rays are those with wave-lengths from 29 to 30. The pigment-producing rays are those with wave-lengths from 29 to 33. Rays with wave-length a little shorter than 29 can produce marked erythema without pigmentation.

Accompanying or following these changes in the skin are others in other parts of the body, but the mechanism of their production is not known. We may attribute them to the absorption of substances formed by the action of the rays on the epidermal cells. One of these substances is activated cholesterol. Some of these changes are known. One of these is an increase of the calcium and phosphorus content of the blood; more are absorbed from the alimentary canal. The calcium content of the blood cannot be increased by taking calcium compounds by the mouth. Hence this method of administration is of little value unless the skin is irradiated by ultra-violet light. The red blood corpuscles and hæmoglobin are increased by a course of exposure of the skin to the rays.

Another very important change is an increased power of the irradiated body to combat chronic infection. Eidenow has shown that the bactericidal power of the blood of animals is increased by irradiating the skin.

In man, however, the bactericidal power of the blood is usually high, but it is possible that the gain in power to deal with infection may be due to the absorption of proteins which may be formed by the destruction of the protoplasm of the epidermal cells, the action perhaps being akin to that of protein shock.

The ultra-violet rays, or the products of their action on the epidermal cells, stimulate the nerve endings. In this way the organs of the body and their blood supply may be influenced by reflex action. The dilatation of the subepithelial blood vessels is an axon reflex (Dixon). It is likely that there are other forms of reflex action. The internal secretion of the ductless glands may be influenced. The nature of the influence—whether stimulation or depression—and the wave-lengths which are most potent for the production of different effects are at present unknown, and need investigation by the experimental physiologist.

Our knowledge of the physiological properties of ultra-violet rays is insufficient to enable us to foretell with accuracy all the diseases which can be successfully treated. Most of what we know regarding the therapeutic properties of these rays has been learnt by clinical experience. The power of the rays to produce erythema renders them useful in the treatment of inflammation of the skin when the state is chronic and the blood supply poor. The *direct* bactericidal power of the rays renders them of some additional use in local infection, although this action is very restricted on account of the slight penetrating power of the germ-killing rays. The production of local erythema is of use in the treatment of referred pain. Relief may be procured by a process of the nature of counter-irritation. The increased power of the body to deal with infection after administration of the rays renders the treatment of value in cases where the resisting power of the body is enfeebled, as in conditions of debility after fevers or local infection. The increased absorption of calcium and phosphorus following general irradiation renders the treatment of value in certain types of bone disease, and, if suppuration is present, there is an additional indication by reason of the enhanced power of the body to combat infection.

Thus it is mainly by *indirect* action that the ultra-violet rays bring about therapeutic action. Obviously it must be by indirect action when the disease is deeply situated and beyond the range of penetration of the rays. But even when the irradiated skin is the seat of disease it is almost always by indirect action that therapeutic results are obtained. These results can be obtained by exposing the skin of other parts of the body and leaving out the affected part. It is only in a very few diseases that local treatment of the affected part gives some benefit, and even in these the treatment of other areas of the skin—that is, *general* treatment—is of more value than the local.

Apart from their power to activate cholesterol and increase the absorption of calcium and phosphorus, and perhaps their power to increase the resistance to infection, none of the known therapeutic properties of ultra-violet rays are peculiar to them and not possessed by some other agents. Many of the maladies for which the rays are recommended by various workers can be treated just as well, or better, by other physical or electrical or thermal agents. I say this with no intention of disparaging ultra-violet ray therapy. Indeed, this form of treatment is capable of yielding results such as a feeling of well-being, increased mental vigour, heightened resistance to infection, and other good effects in which the *modus operandi* of the rays is difficult to ascertain. Even for the production of results which can be obtained by other methods the rays are convenient and frequently efficient. But if we treat by ultra-violet rays all the cases that do not respond to drugs or expectant treatment we shall not obtain a good balance sheet of success and failure.

With regard to apparatus, there is no lamp which emits heat, light, and ultra-violet rays of every wave-length. Different lamps give different selections of all three. So far no essential difference has been established between the results obtained by the use of one

type of lamp as compared with another. The plain carbon-arc lamp emits much heat and light, but the proportion of ultra-violet rays is small. Consequently the exposure of the patient is lengthy. By coring the carbon with certain metal salts the exposure can be reduced, but white fumes are given off, and these make the air cloudy and the objects in the room are gradually covered with a thin film of white powder. Lamps with tungsten electrodes are open to the same objection; their output is poor in heat rays but rich in ultra-violet rays. The lamp which I recommend is the mercury vapour lamp. Its output is rich in ultra-violet rays but poor in heat rays. It gives off no fumes. It is a clean, cold lamp. It works automatically, needing very little attention. Patients feel no warmth when under it, and they may complain of chilliness during treatment, especially in the winter months, unless the room is adequately warmed. A lamp of full size should be chosen. Small lamps are not of much use. Treatment of relatively small areas of the skin can be given by their means, but too much time is occupied when general treatment is required. For local treatment of less accessible regions such as the nose, throat, etc., a special lamp, the water-cooled mercury vapour lamp, and quartz rod applicators, are used. It is also necessary when long exposures are to be given to cutaneous lesions and exsanguination of the skin is required. This type of lamp will only be needed by those who practise ultra-violet ray therapy as specialists.

I shall now describe what I think is the simplest and one of the most effective ways of administering ultra-violet ray treatment to the patient. It must first of all be realized that *general treatment*—that is, the exposure of the entire skin or large areas of it—is necessary in almost all the diseases which can be benefited by the rays. General treatment is required if the disease is general, even if its manifestations are local. It is necessary even if the disease is local. Only in a very few local diseases is local treatment advisable.

The patient, divested of clothing, except that covering the genitalia, should lie horizontally on a couch on his back, his eyes protected by goggles. The lamp should hang three feet above the middle of the body, but a little to one side, so that if the lamp should break the hot mercury will not fall on the skin. At his first visit give a two minutes' exposure to the anterior surface. Then turn him on his back and give the same length of treatment at the same distance. Repeat the treatment every other day, increasing the exposure by half a minute at each successive visit until he receives ten minutes to the front and ten minutes to the back. This will complete a course of treatment. This method will, in the great majority of patients, cause little or no erythema, scarcely any desquamation, and no pigmentation. If erythema is caused it is faint and transient, lasting for a few hours only, and disappearing before the next treatment. Should it be noticed when the patient comes for his next treatment, he should receive no further application until it has disappeared; his next dose should be no larger than the preceding one. Should it be found necessary to give a longer course, time can be saved by bringing the lamp nearer the patient—say two feet. If this is done the exposure should last, not ten, but five minutes.

Children should receive an exposure of one minute at their first visit, and it should be increased by half a minute at each successive visit. In the case of infants the initial exposure should be half a minute and subsequent exposures should be increased at the rate of a quarter of a minute for each successive treatment. These figures are only intended to provide a rough guide. If, on any occasion, the patient interrupts his course, the practitioner, when resuming the application, must take note of the length of the intermission and reduce the length of the next exposure in accordance. If the interval has been as long as two weeks or more he should resume with the initial dose.

Local treatment can be practised to a limited extent with the mercury vapour lamp. The action of the rays can be restricted to the affected area of skin by shielding the skin in the vicinity by black paper. When

giving local treatment it is usually necessary to increase the dosage so as to procure evident erythema. The skins of different patients vary greatly in their sensitivity to the rays, and the dose which would cause slight erythema in one might procure intense redness and subsequent blistering in another. The best way to avoid this is to make a series of test exposures on small areas of skin. Four small windows, each being one inch square, should be cut fairly close together in a sheet of black paper. The paper should then be wrapped around the forearm and the four areas of uncovered skin exposed to the rays, the lamp being at a distance of two feet. These areas should receive one, two, three, and four minutes' exposure respectively. At the same hour next day the areas should be examined. The length of exposure to the area in which there is distinct redness should be the length of treatment to the affected region.

The diseases which may be treated by ultra-violet rays I shall classify in three groups. The first includes those in which the treatment will always effect a cure. The second contains those in which the treatment will generally effect a cure, either alone, or in conjunction with other forms of treatment. The third includes a large number of diseases or cases, mostly common and obstinate, for which the treatment is now being tried. In these diseases the insufficiency of experience renders it difficult to say whether the rays are of real use. To these groups I shall add a fourth, which will include those in which the treatment is likely to produce harmful results.

Group 1.—The disease which must be given pride of place in ultra-violet ray therapy is rickets. For this the treatment may justly be regarded as a specific. I do not know any other disease for which it is a specific, although tetany and laryngismus stridulus—when occurring in rickety children—are said to respond equally well.

Group 2.—In this group I would place first the cases of infants who are unable to assimilate their food, and who consequently waste. If no organic disease is present the major number begin to thrive and put on weight. The treatment must be applied very cautiously and minute doses given. Children who have been the subjects of the fevers which commonly occur during their early years, and are left in a weak debilitated state, respond well to the treatment. Their health improves and they gain in weight. Nasal and bronchial catarrh lessens or disappears, and aural discharge loses its offensive character and may disappear. If the last-mentioned trouble is present, that most valuable form of treatment, zinc ionization, must not be forgotten. Adults who are left in a debilitated state after influenza or similar types of fever improve greatly after ultra-violet irradiation. In surgical tuberculosis the rays can play a valuable part in bringing the disease to an end; but additional treatment is generally required, such as surgery, application of splints, etc., and residence at the sea or in the country are necessary for most cases. For this reason the treatment of surgical tuberculosis by ultra-violet rays in large towns is frequently unsuccessful. In dermatology the disease which is most often treated by the rays is lupus vulgaris. General treatment is more effective than local, though they can be combined with advantage. Local treatment requires the water-cooled lamp. The electrothermic methods are very useful in local treatment, but general treatment should not be omitted. Other infective diseases of the skin, such as impetigo contagiosa and acne vulgaris, respond well. Patients who are liable to boils and carbuncles may be treated by the rays with advantage. Their low resistance to infection by staphylococci can thereby be increased. In seborrhœa I have had some good results in obstinate cases. In true eczema success is not often obtained. The so-called "weeping eczema" (which is really seborrhœa) improves under the treatment, and the "trade eczemas" (which are really forms of dermatitis caused by chemical irritants) can be cured if the causes are removed. Non-specific indolent ulcers should receive a trial of the treatment, both local and

general, and success will often be obtained. Erythema pernio is said always to respond to the rays, but I prefer diathermy. In true psoriasis I have had no success with ultra-violet rays. Some cases of pruritus ani and vulvæ can be freed from the itching. These cases require local treatment, and when it is given every particle of mucus and exudation and previously applied unguents must be removed. Some writers have described good results in the treatment of erysipelas by the rays. I have had no personal experience. In alopecia areata the hair grows again after a course of local treatment by the rays. A long course may be required.

Group 3.—This includes a large number of chronic maladies and obstinate cases which resist drug treatment. The "rheumatic material," such as chronic fibrositis and arthritis, with which the various departments of physiotherapy are so plentifully supplied, has been treated by the rays, but I have had infinitely better results—at any rate in women—by pelvic diathermy. Treatment of chronic fibrositis and arthritis by the rays will generally be followed by disappointment. The ultra-violet rays have been tried in infection of the uterus and its adnexa and the pelvic supporting tissues, erosion, and some forms of dysmenorrhœa, but here again pelvic diathermy gives far better results. In obstinate cases of sciatica and brachial neuritis I have had little success with the rays after other forms of physiotherapy had failed, although it is possible that the cases which had been cured by the latter would have responded to the rays. Hyperpæsis, chronic bronchitis, bronchial asthma, hay fever, Raynaud's disease, acrocyanosis, and other diseases are being treated by ultra-violet rays, and success has been claimed by different writers, but sufficient experience has not been gained to enable a definite statement to be made regarding the therapeutic value of the rays in these diseases.

Group 4.—This includes the diseases and patients for which the rays should be administered with extra caution or not at all. Patients with general pyrexia should not receive ultra-violet ray treatment. In acute local infection the rays should not be applied locally, nor should general treatment be given if the body temperature is raised. If pus is present the treatment should not be given until it has been evacuated. If it is suspected, the treatment should be postponed. In pulmonary tuberculosis the treatment should not be given, except by an expert; quiescent phthisis has been rendered active. It is inadvisable to apply the rays to patients who are suffering from failing hearts or who are the subjects of Bright's disease. It is generally inadvisable to give the treatment to very old people. During menstruation ultra-violet ray treatment should be omitted.

In concluding a short lecture on a very large subject I would insist on treatment by ultra-violet light being under the direction of medical men. Unqualified people, even if they are trained, can only administer the rays, but the doctor can employ them to treat disease.

Migration of Hookworm Larvæ from Cultures.

By CLAYTON LANE, M.D. (Lond.),
LIEUTENANT-COLONEL, I.M.S. (Retd.)

(*Trans. Roy. Soc. Trop. Med. and Hyg.*, January, 1928,
Vol. XXI, p. 309.)

AN important observation, is recorded viz., that in hookworm cultures made after the usual method, there is a considerable migration of larvæ out of the culture. As this fact has not been previously recognised all the existing information regarding length of life of larvæ in soil, the number of larvæ recoverable from a given culture, etc., are of little value as they have been made on untrapped cultures, and the more active these larvæ are the more they are liable to stray. A method of trapping the cultures by placing them in a larger Petri dish than that in which the culture itself is set up is described.

The Treatment of Early Rodent Ulcer.

By J. FERGUSON SMITH, M.A., M.B., Ch.B.
(*The Brit. Med. Journ.*, September 8th, 1928, p. 443.)

REASONABLY early basal-celled epitheliomata can be treated in a large number of ways with a high percentage of successes, but most methods are open to some objection. Adamson's plan of curetting, followed by a massive dose of x-rays, is one of the very best, but it demands apparatus and technique beyond the compass of the general practitioner. The same applies to radium, with the additional drawback that all cases do not respond to it. Diathermy is effective, but cannot safely be employed in the near neighbourhood of the eyeball. Surgical excision is good, provided that a wide margin is possible, though even then recurrence in the scar may be seen. In the neighbourhood of the eye excision may have to be on a mutilating scale, followed by plastic work, and as even then no certain promise of cure can be given, such procedures are, in my opinion, quite unjustifiable. I have in the past used many methods, but for over four years I have treated all my early cases, up to the size of, say, a shilling, by the following simple technique.

The rodent ulcer is ringed with novocain (2 per cent.), and then firmly scraped with a sharp spoon. Only the tumour comes away, and a clean raw area is left. A pencil of CO₂ snow in a vulcanite applicator is applied with firm pressure for sixty seconds, and then a dry dressing is put on. There is considerable oedema of the part for a day or two, but practically no pain at any time, and the ulcer heals rapidly under boric ointment.

The number of cases thus treated and observed for at least six months (the majority for much longer) is sixty-five. Of these, two showed small recurrences at the edge of the scar, where presumably an outlying nodule had escaped destruction. These recurrences were successfully treated by a repetition of the procedure. Recurrence in the depths has not so far occurred. The resulting scars are always very smooth and fine, and in the case of small rodents about the eyelids, or in the naso-labial furrow, almost invisible. The apparatus required is neither elaborate nor expensive, and the technique is exceedingly simple, and there is no reason why practically every basal-celled carcinoma should not be detected and cured by the patient's family doctor. The procedure can be carried out in the consulting room, even on old people, who suffer neither from shock nor pain, and are perfectly fit to go home immediately afterwards.

No claim for originality in this method is made, as no doubt it or something similar is used by many other workers, but I have been moved to write this account by a recent experience of recurrences following radium, x-rays, and excision, in other hands, and by published accounts of methods which I believe to be inferior to the one here given.

Culture and Differential Diagnosis of the Various Leishmanias (Kala-azar, Oriental Sore, Brazilian Leishmaniose) on solid culture-medium.

By MARTIN MEYER & JYOTIS
CHANDRA RAY.

Translated from the "*Archiv. f. Schiffs. u. Trop.*"
Bd. 32. 1928. Heft. 4.

NOLLER had described in 1917 a method for "Blood and Insect flagellates Culture on Plates" in this journal.* In this fundamental research he was able to show that it was possible to obtain by his method cultures of a series of different trypanosomes on plates, especially those from cattle, sheep, birds and frogs, as well as *Schizotrypanum cruzi*, *Leishmania donovani* and insect flagellates. Remarkable about this work was not

so much the fact of his having obtained successful protozoan cultures, but that it was noticed that the flagellate colonies showed varying growth depending on their source of origin, so that a differentiation of the various species was possible.

After Noller's work, there appeared a few more works from him and his pupils who limited themselves chiefly only to trypanosomes.

We were able to begin a comparative study of the different leishmanias only after a sufficient batch of cultures was put at our disposal.

Technique.

The technique employed was scarcely anything different from Noller's. The culture-medium used was:

Agar	..	30.0 gm.
Grape sugar lightly alkaline	..	20.0 gm.
Liebigh broth	..	100.0 gm.

The higher proportion of agar proved to be better than Noller's formula for plate-agar. Sterile, defibrinated horse blood was added to an equal quantity of prepared agar, distributed in sterile test tubes and remelted. The mixture was poured out into Petri dishes 2.5 cm. deep specially made for this purpose. The plates were put inverted in a refrigerator and were inoculated with streak culture. The condensation water was removed from the lids with a 2 per cent. sublimate lotion and the lids were filled with a small quantity of sublimate lotion, according to Noller, to retain the humidity. The bowls were then kept at a constant temperature of 24°C.† in the inverted position, and the lid was cleansed and refilled every third day with sublimate lotion. It is impossible to avoid contamination through air bacteria in spite of utmost precautions taken. The only way to remedy it is to prick them out.

We used for our experiment the following batches of cultures:

- I. *Leishmania donovani* (Kala-azar). 3 batches.
 - (i) Batch Mayer-Werner, 1914, from the peripheral blood of a kala-azar patient from India in the Tropical Institute at Hamburg.
 - (ii) Batch Sulimad, February 1924, from the peripheral blood of an Indian patient in the Tropical Institute at Hamburg.
 - (iii) Batch Assimoody, November, 1925, from the peripheral blood of an Indian patient in the Tropical Institute at Hamburg.
- II. *Leishmania tropica* (Orient Sore).
 - (i) Batch Palastina: received December, 1926, through Professor Noller, Berlin, from Dr. Theodor, Jerusalem.
 - (ii) Batch Turkestan Jessner, received 1927, through Prof. Jessner. Königsberg who isolated it from a patient.
 - (iii) Batch Turkestan Moschkowski, received 1927 from Dr. Moschkowski—Moscow.
- III. *Leishmania tropica*, var. *Americana* (Brazilian epidermal and mucous membrane Leishmaniasis).
 - (i) Batch Dr. Buss, received 1927 from Dr. Buss, Sao Paulo, Brazil.

All these batches were cultured further in the condensation water of NNN-agar medium at room temperature since the receipt, or isolation of original stock. The inoculation of the first plates was from these cultures, later several times direct from plates without any difference being noticed.

I. Kala-azar (*Leishmania donovani*).

Noller had already made attempts at a culture of the Mayer-Werner batch. By sufficient moisture, the colonies go out to the agar surface also in NNN medium test tubes and are to be seen as round, greyish-white colonies when isolated, or as greyish-white strings they flow together—it was not to be wondered that

* Noller, W., Blut- und Insektenflagellatenzucht auf Platten. *Archiv. f. Schiffs. u. Trop.*, 1917, Bd. 21, p. 53.

† Variations in temperature influence the growth in varying degrees.

they grow prolifically on the Noller-plates. Noller described his results as follows:—

"It appeared after 16 days (the plates were kept at $+22^{\circ}$ to $+25^{\circ}$ in the dark) as a bluish grey white growth containing pure leishmania substance spreading out 4–5 mm. beyond the inoculated streak. The flagellates on the plates are always a bit smaller than in the condensation fluid, possess flagella and are actively motile. New plates inoculated with a needle full of this culture each time gave in 7 to 10 days' time, a compact grey streak, spreading 3 mm. beyond the line of inoculation and are limited, round, and smooth edged. There is usually no branching; now and then a few pseudopodic bulgings are noticeable. It is only on exceedingly moist plates, 35 days old, that we notice short parallel branches running out 1 to 3 mm. long, 0.3 to 0.5 mm. broad. If one inoculates a new plate with a bent needle a few needle-fulls of the culture and spreads evenly over the whole plate then in 2 to 3 weeks the whole surface is covered with thick greyish white fluff."

We would completely corroborate Noller's statements through our tests with all the three batches of kala-azar cultures; within a week in our case we got a thick, greyish white, spotted, shining layer with smooth edges. Characteristic is the limited lateral expansion in as far as the culture even after 3 weeks did not spread 3 mm. each side of the inoculating streak. We noticed after 3 to 4 weeks the bulging described by Noller as well as the small runners. We never saw large runners.

Under the microscope, we saw in Giemsa dry slide—that most of the flagellates were thick and short, among them a few slim ones just as we see in large quantities in relatively fresh NNN culture. The protoplasm takes on a rather light stain and behind the nucleus lie often a few dark diffused granules. The ill-defined nucleus lies often to one side, at other times in the middle and takes half of the area of the cell. The parabasal body is in most cases a rod transversely situated. The flagellum springs from the rejuvenated anterior part and is twice as long as the body.

II. *Leishmania tropica*, batch palastina.

In this variety, there develops first of all a thick layer along the original inoculations streak, then a somewhat thinner streak concentrically around this and often a third still thinner zone around the second. When expansion in this form, mostly in clear concentric layers, has reached 10 to 14 mm. each side of the inoculation streak, which generally is the case after 12 to 14 days, we noticed first a uniform indentation of the edges; these grow later to long, often bent, but *never branching* runners. The runners are strong and run out at right angles to the long inoculation streak and when a short streak is made as in the case of double bowl culture, they run radially from the centre to the edge of the bowl. The growth in the presence of sufficient moisture is almost unlimited till it reaches the edges of the bowl in a manner similar to many bird trypanosomes.

Fixed in warm sublimate alcohol and stained after Heidenhain "Klatschpreparate," the runners show closely arranged thick irregular parasites lying side by side like epithelium of cubic shape on the side of the runners, many in the process of division with their flagellum bent with their ends towards the periphery. At the apex, a few flagella are to be seen free in the lumen.

The flagellates gained from the runners after washing in saline solution are pointed oval and very motile; in a Giemsa dry slide they show a light blue stained protoplasm and broadly oval in shape. The nucleus is sharply defined and often fills up the whole cell body; the parabasal body is rod-shaped and sharp. The flagella are very fine and about $1\frac{1}{2}$ to 2 times as long as the body.

Leishmania tropica Turkestan.

(1) Batch Jessner (Konigsberg). This grows precisely in a similar manner as the kala-azar type, in thick smooth shining layers which after a period of 8

days overspread 4 to 5 mm. on each side of the inoculation streak; but after about 10 days another thinner layer grows around the first layer, which shows at first a fine indentation of the edges and later net-like intertwining runners.

Under the microscope, we see a characteristic form in "Klatschpreparate." The edge of the runners as well as the network are composed of slim flagellates in a narrow layer, then follows a large number of round, dark-stained, forms without flagella in process of division, lying always in between interwoven rows of slim flagellates.

We see in Giemsa dry slides oval flagellates with pointed tail ends. The protoplasm is very dense, deeply stained and appears "frilled." In between we see many forms in the process of division arranged in rosette and flagellates in the process of disintegration. The nucleus is not sharply defined, the parabasal body is rod-shaped and lies across and flagella are relatively short.

II. Batch Moschkowski.—Moscow.

Grows similar to batch Jessner, but much thinner, almost like gossamer. After some time it also forms a net-like, intertwined runners, which are still finer and thinner and the single threads look like stringed pearls. It gives the impression as if it always first builds a small round colony, to which another new one attaches itself.

We see in "Klatschpreparate" that these fine strings are composed microscopically of a very thick matting of very slim flagellates, with very long and broad flagella.

In this plait-like matting lie the parasites bent slightly, but almost all of them lying in the same direction, very like a shoal of fish. We find a few isolated young unflagellated forms in process of division; just as Jessner's batch, scarce at the border, in larger numbers in the middle, but they are never so profuse as in Jessner's batch.

The Giemsa slides show a seemingly long and slim flagellum, which takes on a pale weak pink stain. The nucleus is very thick, and bulges out the protoplasm in its neighbourhood. The parabasal body is small and in most cases lying along one of the edges. The long flagellum, thrice as long as the body, is broad and ribbon-like. This powerful development of the flagellum explains also the peculiar growth.

Leishmania tropica, var. *Americana*.

The batch from the Brazilian mucous membrane leishmaniasis differs from the other three oriental boil batches in as far as it forms *no runners*. It shows a thin almost chiffon-like growth, the layer sometimes shows a little ruffling after a long time, the borders are always smooth and undented. The thin growth is not due in any way to an unsuitable culture medium, but to a strong rapid spreading superficial growth; within 10 days the culture spreads 1 cm. on each side of the inoculated streak.

The "Klatschpreparate" explains the form of growth without runners in the way that the flagellates show no tendency, right up to the furthest border, to wander outwards through spreading out their flagella. There are several thick rosettes of growth to be seen all over with the flagellate pointing inwards, specially at the edge where the layer is somewhat thinner. We can notice that it is always the thick flagellate bodies that are situated in an centripetal direction.

The Giemsa slides show the flagellates broadly oval with very dense dark brown stained protoplasm. The nucleus is mostly undefinable—the parabasal body is black, round and mostly along one of the borders. The flagellum is fine and mostly twice as long as the body.

Summary.

The cultures on horse blood-agar plates, after Noller, gave characteristic difference in growth among the organism of kala-azar and various batches from oriental boils and Brazilian leishmaniasis.

(1) *Leishmania donovani* forms, narrow thick layers without proper runners.

(2) *Leishmania tropica* from Palestine grows profusely with broad, parallel never-branching runners.

(3) Two batches of *Leishmania tropica* of Turkestan origin showed absolutely similar very strong runners, formation in the form of intertwined network, the first grew profusely and the other delicately.

(4) *Leishmania tropica* var. *Americana* from Brazil grow chiffon-like thin, without runners, but rapid superficial growth.

The microscopic examination showed the edges in all types to have characteristic groupings, divisions and forms of the parasites which well explain the various forms of growth. The dry slides also show the differences in the flagellate types regarding growth, form, staining and structure of the nucleus and flagellum.

The test gave the utility of this culture method for differentiating between the closely related blood flagellates and should be repeated on a larger scale with the other leishmania batches.

Studies on Malaria, with Special Reference to Treatment.

Part IX. Plasmoquine in the Treatment of Malaria.

By J. A. SINTON, Major, I.M.S.,

AND

W. BIRD, R.A.M.C.,

(Ind. Journ. Med. Res., July, 1928, Vol. XVI, p. 159.)

Treatment of Benign Tertian Malaria.

ALL the patients were suffering from chronic benign tertian malaria and the disease was diagnosed by the finding of *P. vivax* in the peripheral blood immediately before the commencement of treatment. As in our other work a preliminary purgation with calomel and magnesium sulphate was given before the commencement of any course of treatment.

Plasmoquine.

The original communication received from the makers recommended the following course of treatment:—"The daily dose of 0.02 grm. plasmoquine, 3-4-5 times, should not be given more than 5 days in succession. The after-treatment is carried out in the same manner as that of quinine, viz.,

For 5 days plasmoquine.

4 " rest.

3 " plasmoquine.

4 " rest.

3 " plasmoquine.

4 " rest.

2 " plasmoquine.

5 " rest.

2 " plasmoquine.

5 " rest.

2 " plasmoquine.

5 " rest.

"Precautionary measures:—When convulsive pains of the stomach or cyanosis of the lips are noticed after the administration of plasmoquine, it should immediately be stopped and only given again when symptoms have completely disappeared."

The recommended treatment, therefore, consisted of 17 days of treatment and 22 days rest, a total of 39 days, provided more rests were not required on account of toxic manifestations.

Series PM. 1.—The dosage recommended for strong adults was 0.06 to 0.10 grm. daily. In our cases the doses were graded as follows:—Patients weighing 7 stone received 0.05 grm. daily; those of 8 stone 0.06 grm.; those of 9 stone 0.07 grm.; those of 10 stone 0.08 grm.; those of 11 stone 0.09 grm. and those of 12 stone or over 0.10 grm. The majority of our patients weighed about 10 stone each, so the usual daily dose was about 0.08 grm. on the days when treatment was given or an average total dosage of 1.26 grms. per

patient. The spacing of the doses was as recommended above.

Twenty-nine patients were placed on this treatment and in two of them it was discontinued on account of persistent toxic symptoms.

Series PM. 2.—It was suggested in one of the circulars issued by the makers that better results might be obtained if the drug was administered continuously, as far as toxic symptoms would permit. It was, therefore, decided to try a series of patients on a "continuous" treatment, to last until the drug had been given on 28 days with as few rests as possible.

Twenty-two patients were started on this treatment, in which the daily dosage was 0.08 grm. plasmoquine irrespective of the weight of the patient. The total amount of plasmoquine received by each patient was 2.24 grms. and the time needed to complete the 28-day course varied from 28 to 53 days, with an average of 36 days. In two cases treatment had to be discontinued.

Plasmoquine Compound.

Eichholtz (1927), as a result of animal experiments, considered that quinine tended to lessen the toxic effects of plasmoquine. Manson-Bahr (1927b) and Schulemann and Mcmmi (1927), from their study of the use of the drug on malaria patients, considered that the addition of quinine to plasmoquine was useful in preventing the cyanosis sometimes seen during treatment. For these reasons larger daily doses of plasmoquine were used in these series of experiments.

Series PMC. 1.—The patients in this series were treated with daily amounts of plasmoquine compound equivalent to 0.10 grm. plasmoquine and 1.25 grm. quinine. The spacing of the doses was as in the PM. 1 Series, so that the total amounts of plasmoquine given during the 17 treatment days was 1.70 grm. per patient and of quinine 21.25 grms.

Fifteen patients were placed on this treatment and of these one was unable to complete the course on account of toxic symptoms.

Series PMC. 2.—The twenty patients in this series were given a "continuous" course similar to that of the PM. 2 Series. The daily dosage of plasmoquine was 0.10 grm. and of quinine 1.25 grm. making a total of 2.8 grms. plasmoquine and 35 grms. quinine during the 28 days of treatment. The time needed to complete the course varied from 28 to 52 days with an average of 37.5 days per patient. All the patients completed treatment.

Results of Treatment in the Prevention of Relapse.

Relapses were diagnosed as heretofore by the finding of parasites in the peripheral blood by the thick-film method of examination. These examinations were carried out weekly for at least eight weeks after the completion of all treatment (Sinton, 1926a).

Plasmoquine Treatment.—Eight patients out of the twenty-nine in the PM. 1 Series relapsed after treatment and two failed to complete the treatment on account of toxic symptoms. One case was lost sight of before the end of the period of observation after treatment. The observed relapse rate was 35.5 per cent. with a possible maximum of 38 per cent. and an observed minimum of 34.8 per cent. (*vide* Sinton, 1926b, p. 583).

Three patients out of the twenty-two in the PM. 2 Series relapsed and two others were unable to complete treatment because of toxæmia. The failure rate in this series was, therefore, 22.7 per cent.

Plasmoquine Compound Treatment.—Out of the fifteen patients in the PMC. 1 Series two relapsed and one could not complete treatment. The relapse rate was 20 per cent.

Eighteen of the twenty patients in the PMC. 2 Series completed treatment without relapse, while the remaining two were lost sight of at the end of the 5th and 6th weeks of observation after treatment. The after-histories of these two patients were traced and it was found that they had shown no clinical signs of malaria up to the end of two months after we lost sight of them.

One patient who was admitted for malignant tertian malaria received 0.16 grm. plasmoquine daily for 7 days,

but relapsed with the same infection. He was then re-treated with 0.10 grm. plasmoquine and 1.25 grm. quinine daily for 7 days, but on this occasion relapsed with benign tertian malaria in spite of the two courses of plasmoquine.

Quinine Treatment (Control).—The observed relapse rate of 111 patients treated with quinine was 77 per cent. During the last five years over 1,000 patients suffering from benign tertian malaria have been treated in this enquiry by means of the various cinchona alkaloids with a relapse rate of about 70 per cent.

Discussion of the Results of Treatment.

Among the fifty-one patients treated with plasmoquine alone, the relapse rate averaged about 30 per cent. It was found that as the duration of treatment was increased from 17 to 28 days, the relapse rate fell from 36 per cent. to 23 per cent. Muhlen (1926) reports a relapse rate of 31 per cent. after plasmoquine as compared with 59 per cent. after quinine.

Amongst the thirty-five patients treated with plasmoquine compound, the relapse rate was only 8.5 per cent. The rate amongst the patients who received the shorter course was 20 per cent. as compared with no recorded relapses among those who received the longer course.

The relapse rate amongst the eighty-six patients treated with plasmoquine alone or in combination with quinine was only about 21 per cent. which is a remarkably low rate when compared with that amongst the controls and with those of other workers on treatments with quinine (Stephens, etc., 1917-1919; Acton, etc. 1921).

The combination of quinine with plasmoquine seems to be a distinct advantage and the results of the last treatment with plasmoquine compound are so remarkable that they will require confirmation on a larger series of patients.

There seems, however, to be no doubt that in plasmoquine a distinct advance has been made in the treatment of chronic benign tertian malaria, but, as will be seen from the section on toxic symptoms, the margin of safety in the dosage of the drug seems to be small.

The Effect of Treatment on the Prevention of Relapse in Malignant Tertian Malaria.

Most observers have found that while plasmoquine produces very beneficial effects in benign tertian malaria, its action is much less marked in the malignant tertian type of fever.

Discussion of Results.—A total of 14 cases suffering from malignant tertian malaria have been treated with plasmoquine alone or in combination with quinine and of these 10 or 71 per cent. have had relapses due to *P. falciparum*. Amongst 7 control cases treated with quinine and alkali the rate was only 14 per cent. Sliwensky (1927) reports 50 per cent. of relapses after plasmoquine treatment (22 patients) and 30.4 per cent. after the compound (125 patients).

Action on Sexual Parasites (Crescents).—*Plasmoquine*: Four crescent carriers were treated with doses of 0.08 grm. plasmoquine daily. In one patient the gametocytes were absent at the end of 24 hours, while in the other three they persisted for 1.3 and 5 days respectively after the commencement of treatment.

Plasmoquine Compound.—Two patients were given 0.01 grm. plasmoquine and 1.25 grm. quinine daily and in one case crescents were absent at the end of 24 hours, while in the other they persisted for 48 hours. A third patient given 0.08 grm. plasmoquine and 1.0 grm. quinine daily showed these forms for 48 hours but not later.

Toxic Manifestations.

It is evident from the literature that the administration of plasmoquine is liable to be followed by toxic symptoms of a greater or lesser severity even with doses of 0.10 grm. or less daily. In our patients the occurrence of distinct cyanosis or of abdominal pains was considered to be an indication for a rest in the course of treatment and the number of rests affords an indication of the extent of the toxic symptoms encountered by

us. Some cases did not complete treatment, either because of the severity of the toxic symptoms, or because so many rests were found necessary that parasites were not eliminated from the peripheral blood.

Of the twenty-nine patients in the PM. 1 Series, twenty-two needed extra rests in addition to those on the schedule of treatment.

Four of these did not complete treatment. Excluding these four patients the total number of extra days of rest needed was 33 or an average of 1.3 days per patient. The maximum duration of treatment in any one case was 32 days. Of the 33 days rest required, sixteen or about 50 per cent. were required by twelve patients during the first week. Parasites reappeared in the peripheral blood of eleven patients during treatment.

Seven of the fifteen patients in the PMC. 1 Series required extra rests and one did not complete treatment. Among the remaining fourteen patients, the average number of days of rest needed was 1.0 day per patient. Eighty-five per cent. of these rests were needed in the first week. The maximum duration of treatment in any one case was 32 days. In only one case did parasites reappear during treatment.

In the "continuous treatments" twenty-one of the twenty-two patients in the PM. 2 Series needed rests during treatment, and two could not complete the course. The number of days rest required by each patient varied from 0 to 25 with an average of 7.5 days per case. This means that an average of 35.5 days was needed to complete the 28 days' continuous course. Rests were not specially required during the first week as compared with the later weeks and in no case did parasites reappear during treatment.

In the PMC. 2 Series, eighteen of the twenty patients needed rests but all completed the treatment. The number of extra days required varied from 0 to 24 with an average of 9.5 days per patient. As in the previous series, the days of rest were not more numerous during the first week as compared with the later ones, and no case showed parasites during treatment.

Toxic symptoms appeared most frequently about the fifth day of treatment and were usually only cyanosis and abdominal pains of varying intensity. These manifestations might appear separately or in combination. Abdominal pains were usually the first symptom to appear and then cyanosis, but cyanosis was often intense without any abdominal pains. A few patients showed intense pallor of the mucous membranes, especially those of the lips but this was not always accompanied or followed by cyanosis or abdominal pains.

The cyanosis, although taken to be a danger signal, did not seem to cause much discomfort to the patient. One case who had to take 25 days rest in order to complete his "continuous treatment," had intense cyanosis but no other symptoms. This patient was anxious to continue his treatment and complained on every occasion when it was stopped. Another became deeply cyanosed after 2 days of treatment and the condition did not disappear until he had rested for over a fortnight. As a general rule, however, toxic symptoms quickly disappeared when treatment was stopped.

No serious cardiac symptoms were seen but as noted by Barmann and Smits (1927), it was observed that the pulse rate after the first few days of treatment became slower than normal, usually about 65 per minute.

On those days when rests were needed on account of toxic symptoms the urine of all patients was examined as a routine measure. Albumen was detected in only one case, which was undergoing the "continuous" PMC. treatment. The albuminuria disappeared when a rest was given, but reappeared after treatment was recommenced.

Two patients in our series developed symptoms which gave rise to considerable anxiety. The first case was receiving a daily dose of 0.10 grm. plasmoquine and 1.25 grm. quinine, when on the morning of the third day of treatment he developed an ashy-grey pallor with slight cyanosis, vomiting and severe abdominal pains.

He had 12 motions during the day and his temperature rose to 103°F. On the next day his temperature was 102.2°F. in the morning and fell to normal in the evening. The severity of the abdominal pains was less, but he passed over 20 motions during the day and was collapsed. On the following day he had improved and quickly recovered.

The second case, who was on the "continuous" PM. treatment and receiving 0.08 grm. daily, developed even more alarming symptoms. On the 25th day of treatment he was brought to hospital with vomiting, collapse, severe diarrhoea and subnormal temperature, in fact symptoms closely resembling an attack of cholera.

This patient had been quite well when given his last dose earlier in the day and apparently his attack had come on without any warning. He had previously stood the treatment very well and had only required two single days of rest. His condition caused considerable anxiety for some days, but he eventually recovered and did not subsequently relapse with malaria.

The very marked action of sugar and alkali in protecting patients against the toxic effects of stovarsol (Sinton, 1927), suggested that these substances might also protect against the deleterious effects of plasmoquine. To test this possibility, alternate patients were treated with and without these substances, but the results of the two series of 36 patients each showed no very decided differences.

Summary.

The results of our investigations may be summarised as follows:—

(1) After the treatment of 51 patients suffering from chronic benign tertian malaria with plasmoquine only, 30 per cent. relapsed, while amongst 35 patients treated with plasmoquine compound the rate was 8.5 per cent., as compared with about 70 per cent. amongst control cases treated with quinine.

(2) "Continuous treatment" seems to have a greater effect in producing a permanent cure in benign tertian malaria than has the "interrupted treatment," although more liable to be followed by toxic symptoms.

(3) A 71 per cent. relapse rate was observed in 14 cases of malignant tertian malaria treated with either plasmoquine alone or in combination with quinine while amongst 7 control cases treated with quinine and alkali the rate was only 14 per cent.

(4) Plasmoquine rapidly removes all forms of *P. vivax* from the peripheral blood and also the sexual forms of *P. falciparum*, but seems to have little action on the asexual forms of the latter parasite.

(5) Plasmoquine did not have as rapid an effect in the reduction of temperature as did quinine, but when given in combination with the latter drug its febrifuge action is enhanced.

(6) Severe toxic symptoms may follow the use of plasmoquine and the margin of safety with the present dosage seems to be comparatively small.

Conclusions.

(1) The discovery of plasmoquine has marked a distinct advance in the treatment of malaria, but, as pointed out by Manson-Bahr (1927), this drug should be "regarded as the beginning not the climax, of a new series of antimalarial drugs."

(2) In our experiments plasmoquine was much more effective in producing a permanent cure in benign tertian malaria and in abolishing crescents from the peripheral blood than quinine, but in the treatment of attacks of malignant tertian malaria the latter drug is still the treatment of choice.

(3) The low margin of safety in the dosage of plasmoquine renders it necessary that further experiments should be carried out to determine the best dosage, and duration of treatment, before the drug is issued for general use outside hospitals.

Our thanks are due to the Director of Medical Services in India for the facilities which he has placed at our disposal for carrying out this work and to the

Indian Research Fund Association who provided the money to cover the expenses of this investigation.

Gymnema sylvestre in Diabetes Mellitus.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

J. P. BOSE, M.B. (Cal.), F.C.S. (Lond.),

AND

N. R. CHATTERJEE, M.Sc. (Cal.)

(Ind. Journ. Med. Res., July, 1928, Vol. XVI, p. 115.)

Gymnema sylvestre is a stout, large, woody, climbing plant which grows abundantly in Central and Southern India and is also found in Tropical Africa. It is known in Sanskrit as "Meshasringi" meaning ram's horn, in Hindi it is called "Merasingi," in Bengali "Chota-dudhilata," and in Bombay "Kavali" or "Vakandi." Edgeworth noticed that when leaves of this plant were chewed the power of the tongue to appreciate the taste of sugar and all saccharine substances was abolished. This was confirmed later by Hooper who discovered that the leaf also had the valuable property of completely removing the taste of bitter articles such as quinine. The loss of these sensations does not last for 24 hours as was stated by Edgeworth, but only from one to two hours. The root of the plant has a reputation among Hindu physicians as a remedy for snake-bite. The powdered root is generally applied locally to the part bitten and decoction is administered internally.

On account of its property of abolishing the taste of sugar it has been given the name of "Gur-Mar" meaning "sugar destroying" and the idea has gained ground in some quarters that it might neutralise the excess of sugar present in the body in diabetes mellitus. In Bombay and Central India it has been used as a remedy against this condition and wonderful results have been claimed. The present investigation was undertaken to see if the drug really had any effect on the blood sugar in man and animals.

Conclusions.

From the results of its observations we feel justified in drawing the following conclusions:—

(1) The leaves of *Gymnema sylvestre* contain a substance which has a hydrolytic action on cane-sugar. There is also an oxidase-like substance which produces glycolysis in a solution containing glucose.

(2) The extracts made from the leaves of *Gymnema sylvestre* as well as gymnemic acid and its sodium salt have no effect on the blood sugar when given by subcutaneous injections to rabbits.

(3) Powdered leaves and alcoholic extracts prepared from the leaves of *Gymnema sylvestre* have no effect on the blood or urine sugar of patients suffering from diabetes.

The Report on Sanocrysin (Möllgaard) Investigation.

(By The Sanocrysin Research Committee of Japan, 1927.)

THE report on Sanocrysin investigation by the Sanocrysin Research Committee of Japan, constitutes an important contribution to the literature on this subject. An incidental item of interest reported by the investigators is the fact that sanocrysin or at least a closely allied compound, was first obtained by Fodoros and Gelis in 1845 and was used by them in the treatment of syphilis. Its use in tuberculosis is due to the efforts of Möllgaard and his co-workers, whose experiences with this gold salt were embodied in Möllgaard's "Chemotherapy of Tuberculosis" first published in 1924. Since that date an extensive literature has grown up around this subject. From their *in vitro* experiments two of the investigators, Watanabe and Sato, conclude that sanocrysin can inhibit the growth of tubercle bacilli in a dilution of 1 : 10,000, but they find that the preparation in over 0.1 to 1 per cent.

concentration does not injure the pathogenicity of tubercle bacilli—thus differing from Möllgaard with regard to the germicidal action of sanocrysin *in vitro*. The Japanese investigators also record wide divergences from the Danish pharmacologist on the subject of his specific immune serum. The results obtained with sanocrysin in human tuberculosis may be summarised in the workers' own words.

"(1) Sanocrysin used by us was prepared by Dr. Iwatare of the Ban-yu Pharmaceutical Company. From the chemical point of view this preparation is said to be identical with the European product.

"(2) The entire medical staff of the Clinical Department was enlisted, and to each member a number of patients were assigned. In this way a detailed record was kept of each patient. In addition, efforts were also made to obtain as much data as possible on urine, sputum, and Röntgenographic findings. Patients were regarded as 'improved' only when they showed improvement in all these respects. Those with unfavourable Röntgenographic findings were not placed under the head of 'improved,' even though all other conditions were more or less improved.

"(3) In view of the lessons learned from our animal experiments, we avoided using large doses of sanocrysin in a short period of time, as done by Möllgaard. Instead, we injected very small quantities with intervals of over one week between injections. The use of small doses on our part might account for the slight differences between our clinical results and the observations in animal experiments. We never felt the necessity of using the tuberculin immune serum.

"(4) We found that improvement was most frequently observed among light cases, especially of the stationary proliferative type. The outcome was very unfavourable in the progressive exudative type. This point differs strikingly from the result reported by Friedemann. Patients with intestinal or pharyngeal tuberculosis are totally unsuitable for sanocrysin treatment.

"(5) Injections of sanocrysin increase the catarrhal changes in the lesion and thus increase the alveolar sound. In dying patients, even a small amount of sanocrysin produces increased respiratory difficulty. Reinjection of sanocrysin after the improvement of the catarrhal change again engenders catarrh for four or five days. We are inclined to believe that these facts are indicative of the stimulating action of sanocrysin on the tubercular foci.

"(6) Sanocrysin may produce fever, skin eruption, vomiting, diarrhoea, etc., according to the amount injected and also depending on the individual peculiarity of patients. These points should be carefully regulated in using sanocrysin clinically. The use of large doses in a short period of time, as has been done by the originator and his associates, is not only dangerous but also productive of untoward effects. Little secondary effect is produced when small amounts of sanocrysin are injected with intervals of one week or more.

"(7) From the above results, we believe that sanocrysin is not a specific cure for tuberculosis, as claimed by the originator, but it should be regarded as a stimulant."

The Interpretation of Reports on the Cerebro-Spinal Fluid.

By J. G. GREENFIELD, M.D. (Edin.), F.R.C.P. (Lond.).
(*Lancet*, October 6, 1928, p. 716.)

THE examination of the cerebro-spinal fluid is now generally recognised as being of the greatest importance in the diagnosis of cases of organic disease of the nervous system. Sometimes this examination by itself enables an exact diagnosis to be made; more often it serves to indicate which of the two or more possible causes is the basis of the symptoms exhibited.

The Collection of the Specimen.

The examination should, for the patient's sake, only be made once, except in cases which may benefit by the

repeated withdrawal of cerebro-spinal fluid. It should therefore be as complete as possible, and to this end the clinician as well as the pathologist must contribute. Complete asepsis is the first essential, and this applies as much to the collection of fluid as to the operation of lumbar puncture. A contaminated fluid soon changes in character and becomes worthless for diagnosis. Cells and sugar disappear, protein alters, and the fluid gives a fallacious Wassermann reaction. The tube in which it is received must therefore be as sterile as the lumbar puncture needle. Chemical cleanliness is almost as essential. Even the "fur" deposited by boiling instruments and tubes in hard water may upset some of the tests. Whenever possible, distilled water should be used, but water which has been boiled will serve. Attention should also be given to the tube used for the collection. It must be strong enough to withstand the risk of breakage in transit to the laboratory, and should be well stoppered, preferably with rubber or glass. Corks are at best dirty and are apt to form a collecting ground for cells and coagulum.

The amount of fluid to be taken depends partly on the case, and partly on the pathologist. In my experience it is not possible to make a satisfactory examination with less than 5 c.cm. and it is unnecessary to have more than 10 c.cm. even when the quantitative chemical examination is to include glucose, chlorides, urea, and protein. In cases of meningitis or uræmia in which drainage of fluid is beneficial a larger amount will be a convenience to the pathologist. Therefore, if the tubes are marked with a diamond at the levels of 5 and 10 c.cm. it is easy to steer a course between incomplete examination and excessive drainage of fluid.

The Determination of Pressure.

The manometric pressure of the fluid is of such importance that its estimation has become a routine procedure to many neurologists. It is true that an attempt to read the pressure rather complicates the operation of lumbar puncture, but the information it gives is often of the greatest value and can be obtained in no other way. This is especially true in cases of cerebral and spinal tumour where the diagnosis may sometimes be made from the pressure readings alone or from phenomena which are observed in the course of the examination, such as pain at the site of the tumour on jugular compression. It cannot be too strongly emphasised that the rate at which drops of fluid escape on lumbar puncture gives at best a fallacious and at times an altogether erroneous estimate of the fluid pressure. It is generally agreed that in this as in many other clinical examinations, the routine use of the method in normal cases renders abnormal readings more obvious and more convincing by making the limits of the normal more precise; the manometer should not therefore be reserved for the rare cases of cerebral or spinal tumour, but should be used in all cases where lumbar puncture is performed.

In taking a manometric reading it is essential that the patient should be lying on his side with the head at the level of the lumbar spine; he should be breathing easily with his muscles relaxed. Often at first the pressure rises slightly above the normal, but with the patient lying quietly and comfortably it falls in a minute or so to a steady level which is taken as the "initial pressure." Meanwhile the operator notes the dancing of the fluid with the arterial pulse and the slower but rather wider movements which occur with respirations. Normal pressures vary between 100 and 200 mm. of fluid. Pressures above 200 mm., if they cannot be attributed to embarrassment of respiration as in stout or nervous patients, indicate *increased intracranial pressure*. This may be due to cerebral tumour, oedema, or hæmorrhage, or to excess of fluid, as in meningitis or hydrocephalus. It is sometimes possible to distinguish cases of hydrocephalus from those of cerebral tumour or oedema by the observation that in the latter the pressure falls much more rapidly with the withdrawal of fluid. Thus after 3 or 5 c.cm. of fluid have been removed the pressure may have dropped to two-thirds or half of the initial pressure. In hydrocephalus, on the

other hand, so small an amount of drainage produces little reduction of the fluid pressure. It is my rule never to reduce the pressure below two-thirds of the initial pressure, and although quite arbitrary this rule has so far stood the test of experience. The use of a manometer is therefore to some extent a safeguard, especially in cases of cerebral tumour, against the risk of too rapid and too great lowering of intracranial tension. Abnormally low pressures are sometimes encountered, but their significance has not yet been ascertained.

In cases of suspected spinal compression the "Queckenstedt test" is of great value. This consists in getting an assistant to compress the veins of the neck on both sides at first lightly and then, if necessary, more deeply. Normally even light compression causes the fluid to rise rapidly in the manometer tube, falling as suddenly when the pressure is removed. But when the space between dura mater and spinal cord is narrowed or obliterated by tumour or spinal caries or even by meningeal adhesions there is no rise of fluid in the manometer on light pressure and only a sluggish rise followed by an equally sluggish fall results on deeper pressure. Often the fluid does not return completely to the original level, or after rising slowly it may not fall at all when the pressure is relaxed. The latter phenomenon is practically diagnostic of a meningeal tumour. It appears to be due to the ball valve effect of a tumour in the spinal canal, and may be associated with an abnormally high initial pressure. In cases of complete blockage of the spinal canal the deepest jugular compression that the patient can stand, fails to cause any rise of fluid in the manometer tube.

Naked-eye Examination of the Fluid.

Yellow colouration, however slight, is abnormal and indicates either pre-existing hæmorrhage or excess of protein or both. The formation of a *coagulum* on standing is also a valuable indication. In a clear colourless fluid it is characteristic of meningitis, especially the tuberculous and syphilitic forms, or of poliomyelitis. When occurring in a yellowish fluid it indicates considerable excess of protein along with some cell increase.

When a specimen of cerebro-spinal fluid is sent to a pathologist for examination it is advisable that he should be told as much about the clinical nature of the case as possible. This is much better than merely asking him to perform certain tests on it, as most pathologists nowadays are fully conversant with the examination of the cerebro-spinal fluid, and the decision as to the methods of examination to be employed should rest with them. But unless the clinical nature of the case is known some important examination may be omitted or left so late that insufficient fluid remains for the test. The more important lines of examination may, however, be indicated. These will depend on whether the case appears to be one of cerebral or spinal disease and on the acuteness of onset and course of the malady. In every case a total and differential cell count, and an examination for total protein and globulin excess should be made. Where there is any possibility of septic infection a cultural examination and an examination of stained films for organisms should be asked for; these examinations should be made as soon as possible after the fluid is obtained.

In the more acute cerebral conditions it is usually wise to make a fairly complete quantitative chemical examination including estimations of chlorides, glucose, and urea. In suspected meningitis also the chlorides and glucose should always be estimated, as the degree of reduction of these substances gives an indication of the severity of the disease. An estimation of the urea has often proved that cerebral symptoms were due to unsuspected uræmia, a condition in which there is usually also a rise in the chloride percentage. It is a well-established fact that the urea percentages are always identical in the blood and the cerebro-spinal fluid. Consequently the examination of the one makes that of the other unnecessary. In spinal lesions and in many of the more chronic cerebral conditions these chemical examinations are unnecessary, but a Wassermann reaction should

almost always be performed and one of the colloidal reactions (gold, benzoin, paraffin, or mastic) may help to distinguish the type of syphilitic lesion or, in the presence of a negative Wassermann reaction, may indicate that the case is one of disseminated sclerosis.

The minimum examination therefore that may be considered complete in a spinal case or in a chronic cerebral case includes: (1) total and differential cell count (0.5 c.c.m.); (2) estimation of total protein (1 to 2 c.c.m.); (3) one or more tests for globulin excess (0.5 c.c.m.); (4) Wassermann reaction (1 to 2 c.c.m.); (5) a colloidal test (0.1 to 1 c.c.m.). Thus 5 or 6 c.c.m. of fluid are quite sufficient for all these examinations.

X-Ray Diagnosis.

(*Brit. Med. Journ.*, October 6, 1928, p. 617.)

THERE is one real fallacy connected with x-ray work which has grown with the development of radiology, and to a large degree exercises a crippling influence even to-day. Its consequences have been disastrous and far-reaching. It has existed since the beginning, when radiology was looked upon as an interesting toy of the medical profession, when sapient physicians and surgeons impressed upon hospital committees that, of course, the hospital must have some sort of quarters for an x-ray apparatus, but that, equally of course, anyone—medical, pharmaceutical, or otherwise—was good enough to "run the show" as long as he did not spend too much money and was also duly impressed with the diagnostic acumen of his colleagues. This is the false idea which even now survives. No hospital, of whatever kind or size, is regarded as complete unless it possesses an x-ray plant of sorts and an x-ray department. Money can always be found for these. Then the question, the quite secondary question, arises as to who shall take charge of the department and be responsible for its work. In the old days any enthusiast who offered his services was promptly accepted; even now in far too many places the hospital authorities consider that any medical man—or perhaps a layman—is fully qualified, without any special knowledge and without any special training, to be put in charge of the radiological department.

The fallacy—a serious one—is, therefore, that special knowledge is not required to qualify for the very responsible post of officer-in-charge of a hospital x-ray department.

Technique is the first essential for accurate x-ray work. Without it the finest radiological diagnostician must make numerous mistakes; with it his mistakes will be lessened in number, for none of us is infallible, and no method of diagnosis is free from risk of error. The other point, so often overlooked, is that even with the finest technique a man's opinion is apt to prove unreliable unless he has a very comprehensive knowledge of diseases and of the pathological conditions which can give rise to the various findings seen on a screen or recorded on films. The fact that it is possible nowadays to get such magnificent radiographs has made interpretation even more difficult than in the early years of radiology. Much slighter deviations from the normal are relied on as evidence of disease, and more remote regions of the body have been explored. Perhaps the greatest difficulty at the present time is to find specially qualified medical men or women for all these hospital posts.

We cannot agree with those who say that there is no such thing as an x-ray diagnosis. A mere glance on the screen sometimes suffices, while over and over again in practically all the conditions for which an x-ray examination is made the films alone show, beyond dispute, what the pathological condition is. Probably, indeed, no other special method of examination will by itself yield so many positive diagnoses as will the x-ray method. This, however, is not said with a view to urging that purely x-ray diagnoses should be the rule, and we cordially agree that consultation between the practitioner in charge of the case and the radiologist is of the utmost value; if this were always possible many mistakes would not be made.

The League of Nations and Opium.

(*Brit. Med. Journ.*, October 20, p. 711.)

THE Geneva Opium Convention of 1925 came into force on September 25th, 1928; it is now incumbent on the Council of the League of Nations to appoint a Central Board, within three months, to undertake the prescribed duties in regard to international commerce in the substances covered by the Convention, and to arrange for the organization and working of the board and its staff. Provision had been made for the United States Government to appoint one member of the new Central Board; but, in accord with the attitude taken up at the Geneva conferences in 1924-25, from which the United States delegates eventually withdrew, the Council's invitation to participate in the selection of the board has been declined. The reason assigned for this refusal is the inadequacy of the Geneva Convention in regard to limiting the production of raw opium and coca leaves to the medicinal and scientific needs of the world. The United States Government holds that until there can be devised some substitute for the Hague Convention more satisfactory than the Geneva Convention, the eradication of the abuse of narcotic drugs would be more likely to be achieved by strict observance of the provisions of the Hague Convention. The United States will, however, in addition to observing its obligations under the Hague Convention, endeavour to furnish information as the permanent Central Board may request. Meanwhile, at the recent meetings of the Council and Assembly of the League, considerable discussion was aroused by the proposal of the British Government, to set up a fresh commission of inquiry to examine the conditions of opium-smoking and the illicit traffic in opium in the Far East. Objection was taken by representatives of several countries to the expense with which such an inquiry would burden the League, and at first the proposal had a very cool reception. When the French representative urged that the investigation should include China, the Chinese delegate demurred, unless, indeed, the inquiry should cover the commerce in derivatives of opium exported to China from European countries. This inquiry is deemed essential in view of the decision to hold a further conference on opium-smoking in the Far East in 1929. It will be remembered that the Hague Convention of 1912 bound the contracting Powers to bring about the gradual and effective "suppression" of the commerce in opium "prepared" for smoking; whereas the Geneva Convention made such suppression dependent on the prior elimination of smuggling. There can be no doubt that the trade in prepared opium, both licit and illicit, continues to flourish in the Far East. The Federated Malay States, the Straits Settlements, Brunei, and British North Borneo derive no inconsiderable percentage of their revenue from opium-smoking. Further inquiry may be necessary, but action in accord with treaty engagements would seem to be urgently required.

Low Back Pain.

By JOHN T. O'FERRALL, M.D.

(*Journ. Amer. Med. Assn.*, August 25, 1928, p. 532.)

THE subject of this paper suggests the reason for an extremely large number of patients now under treatment by physicians in all branches of medicine and surgery, from the rural physician to the most highly trained specialist. It is at once obvious that the available space hardly permits of even a brief mention of the numerous causes of low back pain, to say nothing of a discussion of them. The frank symptoms of fractures of the spine, osteoarthritis, malignant metastases, and Pott's disease are so well-known that they need only be called to mind in passing. The pains in the lower spinal segments ascribed to focal infections, pelvic or uterine disorders, prostatic enlargement, whether malignant or benign and syphilis represent subjects of much importance worthy of prolonged individual discussion.

It has seemed to me that, in the past, too much stress has been laid on bony abnormalities of the low spine as

an explanatory cause of many backaches, and that the rôle played by the soft parts in their causation has been, to some extent, slighted. It is also believed that the relationship of the various bony structures to one another and to the attached soft parts has not received the consideration deserved.

CONCLUSIONS.

1. The majority of the acute and many of the chronic backaches occur in young adults below the age of 45 as a result of sprain of the lumbosacral ligaments.
2. The strain occurs more frequently in males engaged in laborious work, athletes and others in awkward posture, namely, flexion, semi-flexion and twisting of the torso, especially on impending muscular effort, as lifting and pushing.
3. The lumbosacral joint is normally a most unstable joint and in studying its anatomy insufficient emphasis has been placed on the ligamentous "guy-rope" and the relation of the bony structures to one another, whereas undeserved importance has been given to the bony abnormalities.
4. Gross pathologic changes exist, as hæmorrhage, fibrous adhesions or pannus formation and swelling of the ligaments with pressure on the lumbosacral cord and other parts of the lumbar plexus, protective tonic spasm of the lateral spinal muscles from nerve pressure, and often toxic absorption.
5. Flat roöntgenograms are of little value. Stereoscopic and lateral views of the joint are very helpful and probably essential.
6. Treatment to be effective must represent fixation of the lumbar spine to the pelvis, thoroughly carried out and prolonged for a sufficiently long time to permit healing of the truly sprained ligament and resolution of the pathologic changes that usually occur.

Reviews.

HANDBOOK OF DISEASES OF THE EAR FOR STUDENTS AND PRACTITIONERS.—By Richard Lake, F.R.C.S. (Eng.) and E. A. Peters, M.D. (Cantab.), F.R.C.S. (Eng.). Fifth Edition. London: Baillière, Tindall and Cox, 1927. Pp. xviii plus 310, with 4 coloured plates and 80 figures in the text. Price, 12s. 6d. net.

THIS, the fifth edition, is much the same as its predecessors in general get up. A noteworthy feature of the book is the chapters on the anatomy of the ear. A most excellent account is given of the physiology of the internal ear with special reference to the newest work on the utricle and saccule and the semi-circular canals. The account of vertigo is specially good. The chapters on the operative surgery of the mastoid are also well done. On the whole, for a book of its size, an adequate account is given of the ordinary diseases of the ear, and the book should be a very useful one to those who have not the time for a more elaborate treatise on the subject.

N. J. J.

THE ART OF ANÆSTHESIA.—By Paul J. Flagg, M.D. Fourth Edition, Revised. London: J. B. Lippincott Company. Pp. 384, with 135 illustrations. Price, Rs. 15-12. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Calcutta.

THE "Art of Anæsthesia" is a lucid and well illustrated volume on the subject of anæsthetics and contains a full description of the nature of anæsthesia, the physical signs of the anæsthetised patient, the dangers involved and the danger signals, the various forms of anæsthetics used,—both general and local,—and the relative merits of the various anæsthetics.

A short introductory chapter deals mainly with the history of anæsthetics in which but little reference to the English pioneers of the art is made, and one might think

anæsthesia to be a physical state of entirely American origin.

On the whole it is doubtful whether the book will appeal to readers of English medical literature. It is written in an American style and with reference to American methods which differ in many respects from those in vogue in England. The apparatus described too, is in some cases unfamiliar to the English student. It is, however, certainly an advantage to be enabled to compare the types of apparatus employed in the two countries.

The chapter on the signs of anæsthesia is well written, and indications such as danger signals are well described. A good account is given of the intratracheal, intravenous and rectal methods of administration of anæsthetics.

No mention is made of contra-indications to certain of the common anæsthetics in the various constitutional diseases, such as Bright's disease and diabetes.

T. H. T.

THE CAUSES OF ANTE-NATAL, NATAL AND NEO-NATAL MORTALITY OF INFANTS.—By A. L. Mudaliar, B.A., M.D. Madras: Associated Printers (University Madras Publications). Pp. 83.

"The Causes of Ante-Natal, Natal and Neo-Natal Mortality of Infants" by A. L. Mudaliar, B.A., M.D., consists of three lectures which are elaborated by 14 graphs, and several tables and statistics at the end. The author is to be congratulated on the vast amount of painstaking care and trouble expended in their preparation. It would be easier for the reader to follow the graphs if they were labelled as in the text—Graph I for Hospital A and Graph I for Hospital B. The chart showing the causes of neo-natal mortality in 1,039 cases is open to the criticism that many of the causes of death are more symptoms than causes, e.g., tympanites, pyrexia, etc. This chart is of very little value because, as the author says, "the cause of death could not be accurately ascertained" in the absence of post-mortems.

The second and third lectures consist of discussions on the effects of various constitutional diseases, infectious fevers, malpresentations, antepartum hæmorrhage, eclampsia, etc., in pregnancy. We think that the large part played by eclampsia and nephritic toxæmia is not sufficiently emphasised.

The monograph contains much that is sound teaching, modern and well considered and will well repay the reader for studying it. It is excellently printed and published by the Associated Printers, Madras.

S. A. McS.

MONGOLISM: A STUDY OF THE PHYSICAL AND MENTAL CHARACTERISTICS OF MONGOLIAN IMBECILES.—By Kate Brousseau. Revised by H. G. Brainerd, M.D. London: Baillière, Tindall & Cox, 1928. Pp. viii, plus 210, with 37 figures in the text besides Tables and Charts. Price, 20s. net.

THIS book epitomises our present knowledge of that peculiar variety of mental defect associated with certain well marked physical characteristics which goes by the name of mongolism. The earliest literature on mongolism appeared in England and in America where the type was first recognised as distinct from other forms of idiocy. The first definite description was given by J. Langdon Down in 1866, when he classified the feeble-minded according to their resemblance to ethnic groups, one of which he named the mongol. Dr. Brousseau cites seven theories of the etiology of mongolism, of which she rejects all but one, namely, that mongolism is possibly induced by some obscure disturbance of the ductless glands. She thinks that there may be some inherited or congenital glandular instability or that the mother may develop during pregnancy certain endocrine disorders which may be transmitted to the child. Further investigation may show that mongolism is the result of a pluriglandular syndrome or of the dysfunction of some particular gland because some endocrine disturbance can be demonstrated in every mongol. In mongolism, as in cretinism and achondroplasia, the body is undersized due to a shortening of the long bones, but these shortened

long bones are slender and fairly well formed and show none of the irregularities in growth which characterise the long bones of cretins and achondroplasias. Although mongolism, sporadic cretinism, achondroplasia and rachitis are so markedly different both clinically and pathologically, yet many cases, especially in infancy, present certain resemblances, for the most part superficial, that often cause confusion in diagnosis. Not only scientifically but practically, a correct diagnosis is of great importance since the treatment depends upon an exact diagnosis. As yet no treatment has produced any appreciable change in mongolism and achondroplasia but a correct diagnosis is essential if only to spare parents the disappointment of expecting relief from glandular or other medication that might prove of value if the case were one of cretinism or rachitis.

O. W. B. H.

METHODS AND USES OF HYPNOSIS AND SELF-HYPNOSIS.—By Bernard Hollander, M.D., M.R.C.S., L.R.C.P. London: George Allen and Unwin, Ltd., 1928. Pp. 191. Price, 6s. net.

THIS book does not add much, if anything, to our present knowledge of hypnosis. Dr. Hollander describes the hypnotic state as "a state of exaltation and abstraction" and then leaves his reader to guess what this may mean. The author is more or less in agreement with the views of Bernheim and Sidis that the essential feature of hypnosis is a dissociation of consciousness, but he shares the common error that this dissociation is an artificial state brought about by the hypnotic procedure. Thanks mainly to the work of Freud, we not only know that psychical dissociation is a characteristic of every mind, but also that even in the so-called normal mind the dissociated trends constantly produce manifestations by means of the same psychological mechanism as those underlying hysterical symptoms. With a fine disregard for the light which psycho-analysis has thrown upon the relation between hysteria and hypnosis, Dr. Hollander discusses what he terms the "supernormal phenomena of hypnosis" and never once alludes to the fact that much of what he describes under this caption, has already been studied and described in persons suffering from hysteria. It is only possible to account for this confusion of ideas by noting that Dr. Hollander regards hysteria as a product of "self-hypnosis"! Like so many other professional hypnotists, Dr. Hollander is inclined to exaggerate the therapeutic value of hypnosis. He admits that relapses do occur in patients who have been treated hypnotically but he holds that relapses are not more frequent in hypnotic than in other forms of treatment and goes so far as to maintain that "no other treatment can effect so many rapid and lasting cures." He believes that relapses occur when "ideas are presented to the patient which are not adapted to his individuality." Whatever therapeutic effect hypnosis does produce it is certainly not due to "ideas" passing from the physician to the patient but to the release, while in the hypnotic state, of repressed desires that are finding expression in the form of symptoms and their consequent attachment to the idea of the physician, and this is really nothing else but the replacement of one symptom by another.

O. W. B. H.

HANDBOOK OF SANITARY LAW.—By B. Burnett Ham, M.D., D.P.H. (Camb.). Tenth Edition. London: H. K. Lewis and Co., Ltd., 1928. Pp. xxxii 284. Price, 6s. 6d. net.

THE first edition of this excellent handbook was published in the year 1899 and within 10 years five more editions were published. Since the year 1910 another five editions have been published: in the intervening period of the Great War no fresh edition could be published for 7 years. Since the war and during the last 7 or 8 years 27 new Acts have been passed, and 14 old Acts have been repealed. The edition under review has been, therefore, carefully revised and brought up-to-date. The chapters on "Housing of the Working Classes," "Food" and "Education and Child Welfare" have been entirely re-written, in the light of recent legislation. Several other chapters have been recast, and sections of various

Acts placed under the appropriate headings to which they have reference.

"Sanitary Law" is a very important part of the curriculum for the examination in the Diploma of Public Health. The numerous Acts, orders, bye-laws, regulations, etc., relating to "Sanitary Law" lie scattered in the text-books on hygiene and public health and are therefore, difficult of access. The difficulty of the student is, therefore, removed by this little book in which a very successful attempt is made to collect and condense under various headings the whole of the law bearing upon public health as applicable to England and Wales.

To an Indian student preparing for his D. P. H. examination, this book is particularly very helpful because the Indian legislation relating to public health is based more or less on the English legislation. Even after passing his D. P. H. examination, when he is appointed a Medical Officer of Health, he has to keep himself well-informed and fully acquainted with the ever-increasing and amending legislation, and this book will fully supply his wants at very little expense. His labour will be amply rewarded if he studies this book carefully. In the appendix he will find appointments and duties of Medical Officers of Health and Sanitary Inspectors, and he will learn much by comparing the duties laid down by various provincial enactments in India.

R. B. K.

A SHORTER ANATOMY.—By E. Wolff, M.B., B.S. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis & Co., Ltd., 1928. Pp. viii plus 451, with 130 illustrations. Price, 18s. net.

"A SHORTER Anatomy" is a small volume containing 440 pages of text, and as such is intended to bring down to a narrower compass the lengthy subject of anatomy. The author states in the preface that it is intended principally for those revising their anatomy for the final examinations, but hopes it may prove useful to students at any stage of their course.

The subject-matter is systematically arranged and divided primarily into sections each of which deals with an anatomical region. Each section in turn is subdivided into sub-sections dealing with bony landmarks, nerves, vessels, joints and muscles. Additional sections are given on the vertebral column, and on ossification and epiphyses. The book thus aims at covering the whole field of gross anatomy with the exception of osteology.

The old nomenclature is used, but where the new differs from this it is given in brackets.

The knowledge of anatomical detail required for both the ordinary and the higher examinations in anatomy is considerable, and students presenting themselves for these examinations will require greater accuracy of description and greater attention to the finer points of anatomical relationship than is contained in this considerably abridged volume. One cannot, therefore, entirely sympathise with the author's hope that the book may be of use to a student in any stage of his course except as a supplement to other books. On the other hand there is a great dearth of books on anatomy suitable for students and practitioners presenting themselves for the final and higher examinations in medicine and surgery. Volumes on surgical and medical anatomy are as a rule too brief—and the larger anatomical books far too unwieldy. It is for this latter class of individual therefore that the book is especially suitable. Practical applications to surgery and medicine are given throughout the text in italics.

The transition from the old to the *Basic* nomenclature and the subsequent partial reversion to the old has led to a mixed terminology being used in modern anatomical text-books, which is undesirable. The present volume is not free from this confusion. What was of yore the anterior crural nerve is referred to on page 89 as the femoral nerve with "anterior crural" appended in brackets whilst the same nerve on page 92 is called the anterior crural with "femoral" in brackets. This is only one instance of a defect that pervades the book. It appears to be a matter of some importance that the

modern student should at least know which is the old and which is the new nomenclature.

There are many exceedingly useful illustrations which are clearly portrayed.

Apart from the defects mentioned the book is certainly to be recommended for those requiring to study anatomy as an adjunct to medical and surgical studies for the final and higher professional examinations.

T. H. T.

MOSQUITOES IN RELATION TO DISEASE—INSTRUCTIONS FOR FIELD SANITARY OFFICERS.—By M. O. T. Iyengar. Calcutta: Bengal Government Press, 1928. Pp. 16, with 9 plates.

THE professed purpose of this pamphlet is amply fulfilled. It contains all that the Field Sanitary Officer should know and very practical directions for much that he will have to do.

It is divided up into 11 sections, 7 of which seem to come within the ambit of "principle," and—within that of "practice," and if one may add a word of criticism arising out of the arrangement of the paper, it is that section 2—How to differentiate between the common forms of mosquitoes—should have been placed in juxtaposition to section 10 on the Identification of Bengal Anophelines. There was no reason to separate these essentially cognate matters.

The illustrations are to the point and very well done.

C. S.

LYON'S MEDICAL JURISPRUDENCE FOR INDIA WITH ILLUSTRATIVE CASES.—By L. A. Waddell. Eighth Edition. Calcutta and Simla: Thacker, Spink and Co., 1928. Pp. xvi and 842. Price, Rs. 20.

LYON'S Medical Jurisprudence is too well-known a book to need any general description, but in this new edition there are several changes and improvements and in some parts it is a pity there are not more. These have been made possible by the enlistment of several particularly well-chosen assistants. The greater part of the new additions are due to Colonel Owens—who is somewhat fulsomely described in the preface as "*facile princeps* the foremost medical jurist in India." In many respects he undoubtedly is, but why gratuitously insult others who are engaged in medical jurisprudence work in India by the insertion of *facile princeps*? One of the good features in this new edition is the introduction of numerous photographs from Colonel Owens' collection, which make clear many points better than any amount of written description. Colonel Owens has also revised the chapters on the examination of the dead body, and wounds, and added new and useful chapters on the responsibility of an intoxicated man for his acts, on accident insurance and the Workman's Compensation Act and on gunshot wounds. All this part is excellent, as is also the chapter on blood-stains by Colonel R. B. Lloyd. In this chapter the hæmochromogen test for blood might have been included, as, in the reviewer's opinion, in some cases (blood-stained earth and blood-stains on fabrics the dye of which gives a spectrum which obscures the blood spectrum) this is an easier and more satisfactory test than the cyano-hæmochromogen test described. This is, however, a matter of opinion—*chacun à son goût*—and must not be taken as any detraction from a chapter which as a whole seems to the reviewer all that it should be. The latest investigations of the subject are included and references to recent literature are given. It is written so that a layman can follow the general principles of the various tests and the expert will find it no less useful. The illustration of the blood spectra is a very poor one and the chapter deserves a good coloured plate.

It is a pity that the chapter on Seminal Stains could not have been included in the revision of the blood-stain chapter. The only certain identification of semen is by finding the spermatozoa (and this is only certain when they are found by someone practised in identifying them) but Florence's test is invaluable as a sorting test and is further, at least as good a positive test for semen as many tests relied on for the identification of poisons.

Of this test there is no mention. The putting of Hankin's method as a routine procedure is also, we think, a mistake. It no doubt gave excellent results in the hands of Mr. Hankin but it does not work so well in the hands of others and is altogether too long and cumbersome.

It is in the part of the book dealing with toxicology that a comprehensive revision is most needed and has been least attempted. In a book designed for India where poisoning is so common, one would expect this part to be specially strong. References to recent chemical literature on the subject are here almost non-existent, and the references to cases are mostly before 1900. This is specially noticeable in the figures for the frequency of the various poisons, which, with the exception of a few recent figures for Burma only, are mostly derived from Chemical Examiners' Reports of 40 or 50 years ago. The whole of this part needs a thorough revision and such a revision would be no easy task. We notice, for example, that the paragraphs on ptomaines have been left as in the previous edition, even to an obvious misprint in the second line (found for formed)—ignoring completely a large amount of recent work on the subject and the generally accepted conclusion that ptomaines in the original sense do not exist. In the chapter on arsenic there is no mention of Chapman's work on the arsenic content of fish, to recent improvements in Marsh's test (beyond a bare mention of an electrolytic Marsh's test which is credited to Bloxam) or to the many difficulties in the old test; while Gutzeit's test is not mentioned at all. Under Indian Hemp there is no mention of Bean's test. Numerous other instances might be given.

Amongst the few places where this part of the book has been revised are some excellent new paragraphs dealing with the Cocaine and Morphia Habits and Opium Eating.

A completely new chapter on Life and Accident Insurance by Dr. E. Houseman, not only deals adequately with the subject but contains new matter of great scientific interest. In this chapter a contradiction is given to the statement on p. 52 that "there are no special Indian observations on the relation of height and weight to age."

The two chapters on Unnatural Sexual Crimes and Leprosy in Relation to the Law which in this edition are stated to have been revised by Professor A. Powell appear to be exactly as in the previous edition.

The book is one which everyone who has to deal with Medical Jurisprudence in India must have, and if our criticisms of some parts have seemed carping they may be taken as an appreciation of the excellence of other parts and of the book as a whole.

ADDRESSES ON SURGICAL SUBJECTS.—By Sir Berkeley Moynihan, Bart. Philadelphia and London: W. B. Saunders Company, 1928. Pp. 348. Price, 28s. net.

THIS book contains fourteen addresses on surgical subjects by a very great surgeon, who imparts his lofty ideals and faith in the sacred mission of his art in beautiful, flowing, and resonant prose. The central theme of most of the addresses is that supreme excellence in the art of surgery is not enough, but that surgery is the most powerful weapon of research which reveals the "pathology of the living" and has revolutionised our conceptions of diseases of the stomach, duodenum, gall-bladder, and pancreas.

Sir Berkeley rightly stresses the importance of co-operation between surgeon, physician, pathologist, bacteriologist, radiologist, chemist, and biochemist, if the best results are to be obtained from surgery.

Too seldom is the scene of our endeavours, the operating theatre, graced by the presence of our brother physician or research worker, who by their expert advice could help to elucidate our problems, suggest new methods of approach and help to instigate research on lines dictated by the actual findings in the living. The address delivered before the American College of Surgeons at Montreal on "John B. Murphy, Surgeon" contains one of the greatest perorations which we have

ever read. Masterly descriptions of the various conditions grouped together as the acute abdomen are given in the address on "Perforation of Gastric and Duodenal Ulcers." There are also excellent addresses on "Acute Pancreatitis," and "The Gall bladder and its Infections." In many of the addresses Sir Berkeley voices the feelings of all in unstinted admiration of the two greatest surgeons of all times Lister and Hunter.

The book is well printed, cheap, full of thought, bears the stamp of greatness and should adorn the library of every member of our profession.

H. G. A.

LOCAL ANÆSTHESIA.—By Geza de Takats, M.D., M.S. Philadelphia and London: W. B. Saunders Company, 1928. Pp. 221. Illustrated. Price, 18s. net.

THIS book of 200 odd pages presents in a very readable form the salient points of Local Anæsthesia.

It is really a series of lectures on the subject given to a post-graduate course by the author with dissections on the cadaver and practical demonstrations.

The first two chapters deal with the local anæsthetic drugs used, the types of local anæsthesia, the advantages and disadvantages of local anæsthesia, the preparation of the patient, instruments, and of the solution. Separate chapters describe the various methods in the head, neck, thorax, abdomen, subperitoneal organs, upper extremities and lower extremities.

Only those methods which are free from risk are advocated by the author, and one notices that he does not recommend the paravertebral route for this reason. After describing each method, he presents the percentage of success and failure attending it and gives his advice as to its adoption or not. He recommends the ordinary Record syringe with needles ranging from 3 cm. to 12 to 15 cm. in length, and states that 250 c.c. of a $\frac{1}{2}$ %, 100 c.c. of a 1%, and 40 c.c. of a 2% solution of novocain should not be exceeded. He advises the use of adrenalin mixed with the novocain solution in dosage which varies in different fields, because its use decreases the toxicity of novocain by producing more gradual absorption. There is undoubtedly great scope for this type of anæsthesia particularly as an auxiliary to general anæsthesia. In Calcutta we have had excellent results in upper abdominal work with "abdominal field block" combined with "anterior splanchnic anæsthesia" and a minimum of open ether.

The book is well printed and illustrated with a good index, and we cordially recommend it.

H. G. A.

SCIENTIFIC REPORTS FROM THE GOVERNMENT INSTITUTE FOR INFECTIOUS DISEASES, TOKYO.—Vol. VI, 1927.

THE Scientific Reports from the Government Institute for Infectious Diseases, Tokyo Imperial University, Japan, for the year 1927 are bound together in a stout volume of over 600 pages. They are divisible into seven sections comprising the subjects of Bacteriology and Serology, Pathology, Biology, Biochemistry, Clinical Medicine, Parasitology and Protozoology, and lastly Medical Entomology. It is impossible in a short review to give even a brief account of the variety of subjects dealt with but special mention must be made of the work of Watanabe, Sato and Miyagaza on Sanocrysin. Their results do not bear out the claims of Möllgaard and his school regarding the specific action of this compound on tuberculosis and in this respect they agree in the main with those of numerous other independent workers. S. Kishino records some interesting experiments on the influence of certain salts on the growth of typhoid bacilli. T. Tamiya contributes some important studies on thermal influence upon the Wassermann reaction with a description of the so-called freezing-point method. S. Hosoya and S. Kishino describe and figure a new apparatus for cultivating anærobic bacteria as isolated surface colonies.

In the biological section K. Saito carried out an experimental study on the origin of the oestrous hormone, while in the sections of Protozoology and Parasitology

and of Medical Entomology important work has been done on dog-filariasis and on Japanese mosquitoes as intermediate hosts for *Filaria bancroftii* (Cobbold).

The above notes indicate the extensive range of work carried on in Tokyo: a study of the full papers will repay the research worker:

J. M. H.

CANCER, THE SURGEON AND THE RESEARCHER.—

By J. Ellis Barker. London: John Murray, 1928. Pp. xii—483. Price, 7s. 6d. net.

THE main feature of this book is an attack directed against the surgeon and the research worker who have apparently formed themselves into a union against Mr. Ellis Barker and his work. Who these leaders are, and why they should devote their energies against him is not obvious from reading the book. The mere fact that Mr. Barker is a layman does not appear to be a sufficient reason. One must remember that when a layman speaks on a difficult technical subject, there are bound to be numerous errors that he will make and which are bound to be attacked, not from any personal motive, but purely on account of the fact that he is not able to assess the value of the evidence.

All through the book, these workers are abused as being ignorant, wasteful, etc., but whenever their work coincides with Mr. Barker's views the surgeon is hailed as good, eminent or far-seeing. Mr. Barker has apparently only recently heard that cancer can undergo spontaneous cure.

In the book, we learn that homœopathy and Abrams' box can cure cancer: if this were really so, two years would be quite sufficient to establish the reputation of either method without any press puff. The medical profession cannot stand aside and refuse to recognise any cure.

Mr. Barker has still much to learn, for the quotations that he gives are regarded as gospel truths, and not merely something that has been written in a book or in a paper. The value of such evidence depends a good deal on the integrity of the author. There are human beings who are apt to exaggerate or be biased, and when they write, a few cases become hundreds. Again he does not realise the difference between the partial association and the true causation. The real object of the book is the prevention of cancer by dietetic methods, but no details are given except the views of the writers.

A lacto-vegetarian diet consisting of fresh fruit, salads, wholemeal bread, milk, etc., which are rich in vitamins and mineral substances, is recommended as a preventive measure against cancer. The introduction is by Sir Arbuthnot Lane, the eminent surgeon whose fame is associated with the surgical treatment of intestinal stasis, and there we are informed that cancer is a disease of faulty feeding, and not a mysterious disease that can be fathomed only by eminent scientists who have specialised in microbiology, chemistry and other sciences.

In reading through the book the paste and scissors work which Mr. Barker has done gives us very little real help in elucidating the cause of cancer. The book has obviously been written to increase its sale by controversy, and we trust that the money Mr. Barker obtains will be used to test his own ideas, such as they are, and give humanity the answer to the long sought for solution of the cancer problem. Mr. Barker can rest assured that he will gain, not only the praise he has already given himself for his solution of the cancer problem, but also that of those hard-hearted ruffians, the cell probers and the microbe hunters, who, although corrupt, are still able to distinguish truth from falsehood.

MEDICINE: Vol. VII, No. I, February and No. II, May, 1928.—Published Quarterly. 500 pages to the volume. Baltimore: The Williams and Wilkins Co. Subscription Price, 23s. 6d. net, post free per annum. English Agents: Baillière, Tindall and Cox, London.

ONE can scarcely apply the word journal to this publication. Although it is published in the form of a journal at regular intervals the bound volumes will

constitute more of an encyclopædia on the subject of general medicine, neurology and pædiatrics than a journal in the ordinarily accepted sense. Each number consists of an analytical review, or analytical reviews, of one or more subjects. The authors are masters of their particular subjects. The numbers are issued quarterly and each volume consists of 500 pages. Number I of this year contains articles on three closely allied subjects; their titles are "Hyperplasia of Lymphoid Tissue and Lymphocytosis," "Experimental Study of the Leucemias and Lymphatoma," and "A Review of the Treatment of the Lymphatic Leucemias and Related Diseases especially by Irradiation." Number II is a most excellent monograph, of about 150 pages, on epilepsy.

The printing and paper are good, and the diagrams and illustrations are clearly reproduced. We can recommend this publication to any physician who wishes to keep abreast of the times and to acquire a "system of medicine" which will be valuable to him for the rest of his career.

L. E. N.

A POCKET MEDICAL DICTIONARY.—By G. M. Gould, A.M., M.D. London: H. K. Lewis and Co., Ltd. Ninth Edition, Revised. Over 40,000 words. 1928. Price, 10s. net.

THIS is the ninth edition and the fifty-seventh reprinting of this very useful little dictionary. The words are clearly printed in bold-face type, they are then respelled phonetically in italics and are followed by a very brief definition. As far as one can see the only point that has been sacrificed in order to make the dictionary a pocket one is the definition; this usually consists of only a few words but is in most instances sufficient. The print is clear and not too small and the paper is very thin but opaque. The binding is very satisfactory; it appears to be quite strong, yet the book will lie open on the table and the pages are easy to turn, that is to say they do not stick together. The case is a flexible one and very suitable for a pocket dictionary. The term "pocket" is certainly justifiable, but anyone who is at all fastidious about the shape of his pockets would not, we feel sure, care to carry this book in them for any length of time.

Another feature of this book is the numerous extremely valuable tables which are to be found in their suitable places throughout.

A reviewer in a tropical country naturally first looks up words which are current in tropical medicine; we did this and were very disappointed. "Sleeping Sickness" is described as "a peculiar disease characterised by increasing somnolence. *Encephalitis lethargica*." There is no mention here of trypanosomiasis. The words "Sleepy Sickness" have, we believe, been applied to encephalitis lethargica, but surely for many decades the name "Sleeping Sickness" has been used in reference to the African disease. Trypanosomiasis is given and justice appears to have been done to the genus Trypanosoma, but there is no reference to Leishmania, as a genus, nor is the word Leishmaniasis given. "Leishman-Donovan Bodies" is defined as *Piroplasma donovani*; *Leishmania donovani*. Small parasite-like bodies found in the liver and spleen of patients suffering from kala-azar." There is no mention of any other species of Leishmania. For the definition of oriental sore we are referred to "Furunculus orientalis," which we find is "a disease of the face in the Orient with a circumscribed ulcer on the cheek or at the angle of the mouth." Blackwater fever is described as a "fatal contagious disease of the tropics." We would like to suggest that before the next edition of this book appears it should be revised with the aid of the latest edition of Manson's, or some other book on tropical medicine.

L. E. N.

FILTERABLE VIRUSES.—By Various Authors. Edited by T. M. Rivers. London: Baillière, Tindall and Cox, 1928. Pp. ix plus 428, with 15 plates and 26 figures. Price, 34s. net.

THE filterable viruses are not quite anybody's child. There is a little to be found about them in books on

bacteriology even when this word is used, as it so commonly is, to include any kind of pathogenic organism. But more frequently they are taken under the wing of the protozoologist. We do not know of any university which has established a chair of chlamydozoology yet, but we feel sure that it will not be long before one of the more progressive American universities does so. The subject is one that up to the present has been left mostly to the research worker. It is not surprising, therefore, that the first comprehensive book on the subject should come from the Rockefeller Institute. The book is edited by Dr. T. M. Rivers who also contributes the introductory chapter. There are nine other contributors each of whom is responsible for one chapter; the contributors are for the most part colleagues of Dr. Rivers at the Rockefeller Institute.

Our present knowledge on the subject of filterable viruses is, to say the least of it, sketchy. The evidence for many of the theories that are put forward is very scanty and consequently these theories are not universally accepted. In most instances in this book the various views are given although the writer naturally emphasizes his own special view on the subject. One's first impression might be that the subject is a small one, but one soon realises that, on the contrary, it is so large that an important subject like rabies can only be allotted three pages. Poliomyelitis has on the other hand been dealt with very thoroughly, in one chapter of forty odd pages, as a type specimen of human filterable-virus disease. The victims of filterable-virus diseases are not only man but cattle, birds, insects, plants and even bacteria. In this book the whole range of viruses is dealt with, though the bacteriophage has not received much attention.

The book which contains a very fair statement of our present knowledge on the subject, is well written throughout. The illustrations are useful and there is one excellent coloured plate demonstrating the various specific cell inclusions. It will undoubtedly be accepted as the standard work on the subject and should find its way into every medical library. We would like to make one small suggestion for the next edition and that is that more attention should be paid to the numbering of the plates and figures; some confusion might conceivably arise through at least three plates in different chapters in the book being described as Plate I. Other plates bear no number at all.

L. E. N.

ELEMENTARY PATHOLOGICAL HISTOLOGY.—By W. G. Barnard. London: H. K. Lewis & Co., 1928. Pp. 80, with 176 illustrations on 52 plates. Price, 7s. 6d. net.

THIS is an example of spoon-feeding; but spoon-feeding at its very best. Most of us as students were given pieces of morbid tissue, or at the best were allowed to fish a ribbon of paraffin sections from a dish of water, we were shown the technique of mounting and staining, this we did very indifferently, for the first few classes at any rate, we were then shown a very diagrammatic drawing of what we ought to see, we were expected to correlate the mess under our microscopes with that drawing and identify the various cells and groups of cells. We were not taught that there is anything "inherently indelicate in a curiosity which brings it to bear on a tumour or inflammation" but we were certainly not encouraged to use our oil immersion lens in the pathological histology classes; the sections or the cover slips, or both, were usually too thick for this.

This book consists of about 170 most excellent photographs of sections of the whole range of morbid tissues, commencing with inflammation and ending with tumours. Each photograph has a short but very complete explanation on the opposite page. Besides this there is very little reading matter, but at the beginning of each of the thirty sections, into which the subject is divided, there is a page of introduction. There are also a few very useful diagrams. It is a book which will save the student of pathological histology many days of groping about in the dark, and it should stimulate him to prepare sections equal to those from which these photographs have been taken, rather than provide him with an excuse

for not preparing his own sections. To the post-graduate student who wishes to revise his knowledge of the subject, the book should prove invaluable.

The photographs are excellently reproduced on very good paper and the book is sold at a very moderate price.

It would obviously be out of place in work of this nature to give any details of technique, but we think that a few lines, say in the preface, giving the staining method that was used in preparing these slides would not have been out of place. We should also like to have seen the magnification, or the numbers of the lenses used, noted under each photograph; but the author probably had some good reason for not doing this. The spelling "injest" is new to us, but we feel sure that it must be justifiable as Dr. H. D. Wright concurs.

L. E. N.

AN INTRODUCTION TO EXPERIMENTAL PHARMACOLOGY.—By Torald Sollmann, M.D. and Paul J. Hanzlik. London and Philadelphia: W. B. Saunders Company, Ltd., 1928. Pp. 321, Illustrated. Price, 20s. net.

THIS is an adaptation from the senior author's "Laboratory guide in pharmacology." The book is divided into two chief divisions—chemical pharmacology and experimental pharmacology. The chemical portion deals with solid and liquid pharmaceutical preparations, with lessons in incompatibility, metrology, poisonous drugs, and their antidotes. The chapter on osmotic and colloidal phenomena gives a good summary of the principles of physical chemistry that a student of pharmacology ought to know. The chapter on agglutination, hæmolysis and hæmoglobin changes, briefly deals with all the important items of hæmatology. The nature of protoplasmic poisons, and the simple technique of testing the effect of drugs on unicellular organisms, worms, ferments, etc., are discussed in the last chapter in chemical pharmacology.

The section on experimental pharmacodynamics begins with the first two physiological properties of protoplasm—excitability and contractibility. The physical experiments like Bernstein's experiments, Rhumbler's model, etc., reveal a striking resemblance between physical and protoplasmic movements and will strongly impress upon the mind of the student the nature of infusorial, and amœboid movements. Four chapters are devoted to the study of smooth muscles and the series of nicely arranged experiments with appropriate discussions on them will help the student a great deal in appreciating the complicated physiology of the unstriated muscle.

The movements of the gastro-intestinal tract are fully discussed and the authors have tried to explain the peristaltic co-ordination by the gradient of irritability and by the refractory phase of the muscle itself and discredit the nervous "enteric system" of Langley regulating the pendular and peristaltic movements of the intestines.

In the section dealing with the heart, a brief discussion on general properties of cardiac muscle is followed by experiments demonstrating the technique of perfusion of the hearts of amphibians and mammals. A short note on the assay of cardiac tonics is also added. A review of the autonomic system dealing with the anatomy and principles of localisation of action is very useful for the student.

The methods of studying the bronchial muscles are brought up to date by including some new techniques devised by the author. The perfusion method described does away with the vascular factor—a great disadvantage in other methods. Allergic and glandular reactions are also discussed.

The central nervous system has two chapters devoted to its study, dealing with cerebro-spinal depressants and stimulants. The treatment of poisoning by convulsants is also included.

The last three chapters are devoted to respiratory reactions, and circulatory correlations and changes in urine flow, dealing mainly with the study of the respiratory and vasomotor centres and a discussion on the mechanism of diuresis with notes on perfusion of the kidneys.

Valuable appendices are added containing a description of the requirements of an experimental pharmacological laboratory, doses and methods of giving drugs to animals, and the preparation of physiological solutions. The list of reference books is very useful. A course of pharmacology and pharmacodynamics is also scheduled.

The book is essentially practical and meant for students of pharmacology. The discussions added to the data derived from the experiments are very well arranged and details of physiology are rightly referred to textbooks on that subject. Although meant for students the book is indispensable to independent workers and teachers of pharmacology. The selection of experiments for students when dealing with a subject like pharmacology is difficult, and the vast experience of the authors as teachers has greatly helped them in making a selection. No student or teacher of pharmacology can be without this most valuable contribution to that science.

R. N. C.

RADIATION IN CHEMISTRY.—By R. Alan Morton, B.Sc., Ph.D. (Liv.), F.I.C. London: Ballière, Tindall and Cox, 1928. Pp. xvi plus 284, with 44 figures. Price, 15s. net.

THIS small volume of 284 pages covers rather a wide range of inter-related subjects and as such it has not been possible to go into the details of every aspect of "Radiation in Chemistry." The presentation of the theory of radiations is meagre with only a brief statement of the fundamental laws of radiations and photochemistry. Barring these limitations, the book has been written very lucidly and with a clear exposition of the subjects in view, and it contains useful practical information.

Section I begins with a brief statement of the two rival theories on the nature of radiations—the electromagnetic theory of Faraday and Maxwell, and the quantum theory of Planck, and ends with a short account of the mechanism of photochemical reactions. In sections II and III, we have an accurate account of different types of sources of light and of the various methods of measuring the intensity of radiations. In sections IV and V a few types of photochemical reactions and their applications in photography and allied sciences have been recorded in great detail. The most interesting section, however, from the point of view of medical men is section VII, which deals with biochemistry and light. In these days of actino-therapy the author has done well to avoid the tendency, which has recently become apparent, to exaggerate the curative value of light. On pages 194, 195, we read "the exposure of the human body to sunlight causes an increase in the blood alkalinity," and that this change usually occurs concomitantly with pigmentation of the skin, but the mechanism by which this is brought about is not clear. Later on the author discusses the question of the synthesis of vitamins in the animal organism by subjecting it to different types of irradiations. The book is concluded with a short review of the applications of x-rays in chemistry and medicine. On the whole, the book will be very useful to those chemists and medical men who wish to get a general idea of the nature of radiations and their practical applications.

R. N. C.

APHRODISIAC REMEDIES.—By The Staff of the "Practical Medicine." Published by the Practical Medicine, Delhi, 1928. Cloth, Pp. 215. Price, Rs. 4.

THIS volume is said to be compiled from standard works and articles of eminent physicians and surgeons contributed to the medical journals and books. The book has already run through three editions so evidently there is a demand for it. In the present edition the subject matter has been re-arranged and all new remedies used against sexual debility have been included. The book is divided into four parts. The first part deals with aphrodisiacs used internally; the second part deals with those used externally; the third part gives special methods of treatment recommended by eminent authorities. The

last section dealing with the methods of treatment employed by the indigenous practitioners in India is interesting; there is also a list of Indian aphrodisiac drugs. The book will certainly be of use to practitioners interested in aphrodisiacs.

R. N. C.

THE ENDOCRINES IN GENERAL MEDICINE.—By W. Langdon Brown, M.A., M.D., F.R.C.P. London: Constable and Co., Ltd., 1927. Pp. 144. Price, 7s. 6d. net.

THE author has attempted in this small volume to give a brief account of the endocrine system and its diseases for the benefit of the general practitioner. Few subjects in recent years have so powerfully stimulated interest and imagination as endocrinology and in view of the difficult nature of the subject and the vast amount of literature which has been produced, this book is very welcome. It puts before the practitioner all the knowledge necessary to him for diagnosing and treating cases with disturbed endocrine mechanism. The affections of different endocrine glands are dealt with separately and the author gives many examples from his personal experience by way of illustration. The book is written in simple and lucid style and makes this difficult subject easily comprehensible. We have no hesitation in saying that the book should form part of the library of every practitioner.

R. N. C.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT.—Revised by W. Harrison Martindale, Ph.D., F.C.S. Vol. I. Nineteenth Edition. London: H. K. Lewis & Co., Ltd., 1928. Pp. xxxvi plus 1,207. Price, 27s. 6d.

THE first edition of this valuable book came out nearly forty-five years ago and since then it has gone through nineteen editions. That in itself is sufficient evidence of the popularity and utility of this book. It has been the constant endeavour of the authors to include in new editions all the new drugs and preparations that have been accepted by the profession and this edition contains nearly a hundred more names than the last edition. A very good summary of the claims made regarding new remedies has been given, ending up with a very fair criticism of these claims. All the recent advances made in therapeutics have been touched including the application of liver therapy in anæmia and the production of vitamin D by irradiation of ergosterol.

This edition like the previous ones is an unrivalled book of reference and the profession owes a very great debt of gratitude to the author for the great labour and the trouble he has taken in presenting this accurate and comprehensive summary of the therapeutic agents in use. This is a book which no medical practitioner can afford to be without.

R. N. C.

GESUNDHEITS-RATGEBER FÜR WAERMERE ZONEN.—By Hans Ziemann. Sixth Edition. Berlin, 1928. Pp. 90.

THIS popular booklet is written for laymen living in lonely outposts of civilisation, sometimes far away from medical help. The first three chapters are especially valuable, dealing with general hygiene in the tropics, like housing, food, clothing, water-supply, physical exercises, servants, etc. The following chapters explain the most important tropical diseases, giving the symptoms which may be recognised by laymen. Malaria, yellow-fever, bowel-complaints including the dysenteries, and sleeping-sickness are especially considered. Only that part of treatment and nursing is dealt with which can be carried out without a physician. Special stress is laid upon these symptoms which urgently need trained medical help and the author warns laymen against attempting any line of treatment which can only be carried out by skilled medical men. Of very great value are the very extensive prophylactic hints, which are added to each chapter.

A special advantage is the very short but clear style, which omits all superfluous scientific details. The booklet shows on every page the great personal experience

of the author. There exist an English and an Italian translation.

O. U.

FAVOURITE PRESCRIPTIONS.—By Esplne Ward, M.D. (Belfast). Second Edition. London: J. & A. Churchill, 1928. Pp. 101. Price, 5s. net.

THIS little book is divisible into three sections. The first 13 pages are devoted to a list of pharmacopœial drugs and their preparations: there follows a brief section entitled "Hints for Treatment of Poisoning," while the remainder of the book contains lists of the different prescriptions that have been found useful by the author. Prescriptions coming within the scope of the Dangerous Drugs Act of Great Britain are usefully indicated by the letters D. D. A. in brackets.

The volume should prove of value for ready reference purposes. Printing on one side of the paper only allows of still further prescriptions being added. There are a few errors which will doubtless be expunged from future editions. The printing is good, the book is of handy size and the price is eminently reasonable.

J. M. H.

THE ESSENTIALS OF MEDICAL DIAGNOSIS.—By Sir Thomas Horder, Bart, K.C.V.O., M.D., F.R.C.P. (Lond.) and A. E. Gow, M.D., F.R.C.P. (Lond.). London: Cassell and Co., Ltd., 1928. Pp. 682, with 8 colour and 11 black and white plates and 22 figures in the text. Price, 16s. net.

THE importance of correct diagnosis in any system of treatment cannot be over-estimated. "Diagnosis is half cure" is a well-known adage. To the student and practitioner probing the mysteries of the human structure and its ills, the need of full and accurate data to enable him to diagnose the malady is the first desideratum. It is to guide the student in this direction that the present volume is designed.

The names of the distinguished authors are indeed a sufficient guarantee of the usefulness and value of the book itself. They have brought their wide knowledge and long experience within reach of the novice entering upon the arduous duties of a medical practitioner. To the student who arrives at the wards after going through a curriculum of medical studies, the present volume is indeed a mine of information. It will help him more easily to deal with the clinical aspects of a case and understand more clearly the various factors, such as contours, complexion, attitude and movement which go to make up the study of the human body as a living anatomical and physiological unit. It is especially with this view that the authors have dealt with diagnosis under various physiological heads and in a most elementary fashion. The volume gives concise descriptions of the methods of investigation of cases in practice and tells the reader how to interpret the results of enquiry. Though pathological tests and data receive due attention, greater emphasis is rightly laid on the clinical side of the investigation. The book is intended primarily for the student, but it will appeal equally to the practitioner. The text is copiously illustrated.

S. P. B.

CLINICAL MEDICINE.—By Oscar W. Bethea, M.D., Ph.G., F.C.S., F.A.C.P. Philadelphia and London: W. B. Saunders Co., 1928. Pp. 700. Price, 35s. net.

THIS is an admirable book of handy size in which the author has incorporated the latest and most generally accepted information as to the diagnosis and treatment of about one hundred common diseases coming within the province of Internal Medicine. Unproven theories as to the causation of diseases have been entirely omitted and thus the bulk of the book reduced.

In well-equipped hospitals and in wealthy houses the doctors in-charge get all the facilities of modern science but the vast majority of cases are amongst the poor and cannot even get treatment in the hospitals. Doctors are greatly handicapped in their management of such cases. The author has taken therefore particular interest

in the management of cases wherein the facilities of modern technique are limited. The book will prove of immense value if properly used and the author is to be congratulated on bringing out a volume containing such useful information.

S. P. B.

DIABETIC MANUAL FOR PATIENTS.—By Henry J. John, M.A., M.D., F.A.C.P., M.R.C. St. Louis: The C. V. Mosby Company, 1928. Pp. 202, with 42 illustrations. Price, \$2.00.

DIABETES is one of those diseases, the keynote of success in the treatment of which depends largely on the good sense and intelligent co-operation of the patient. It is essential, therefore, that the diabetic patient should, at any rate, be familiar with the *rationale* and the main principles underlying the treatment of the disease, particularly dietetic and hygienic, so that he will be able to co-operate with his doctor intelligently and wholeheartedly.

Dr. John in this little volume has taken great care to explain very fully the principles underlying the causation, pathology and treatment of diabetes. As a matter of fact, it seems to us that he has gone rather too far when he describes the details of the anatomical and physiological study of the disease. To an average diabetic patient, some of these details would be rather difficult to understand.

The practical details which the author has taken so much pains to give regarding the treatment by diet and by insulin are very useful and will be of much help to all careful readers of the book. The book is profusely illustrated which is a great advantage to the lay reader enabling him to understand the subject matter easily.

Appendix II dealing with sample *menus* and various food-recipes for the diabetic has been prepared by Miss Laura Soden, Dietitian in the Diabetic Department of the Cleveland Clinic Hospital and is an excellent supplement to the book. It gives quite a variety of diet-prescriptions which, we are sure, will appeal to all diabetic patients.

The book will be very helpful to all persons suffering from diabetes, as its study is expected to make the diabetic patient follow his doctor's instructions more intelligently, and thus the end-results will prove satisfactory.

J. P. B.

CARE OF INFANTS IN INDIA: A WORK FOR MOTHERS AND NURSES IN INDIA. London: Messrs. Caldwell, Ltd. Pp. viii plus 92.

THIS little book though primarily an advertisement for the well-known Mellin's Food contains so much useful information about the care of babies in India in a compact form that it could safely be put into the hands of any young European mother who required simple advice for both herself and her child. There are certain minor points with which one could disagree, such as the desirability of giving a healthy infant 2-hourly feeds for the first month of life, and introducing meat into his diet before he is a year old, but on the whole the information given is in agreement with modern medical knowledge and if the directions were carefully carried out, the Anglo-Indian infant mortality in this country would be considerably reduced. Small books in the vernacular on the same subject but with modifications on the diet questions are greatly needed by Indian mothers.

G. S.

INTERNATIONAL CLINICS. (A QUARTERLY JOURNAL).—Edited by Henry W. Cattell, A.M., M.D. Philadelphia and London: J. B. Lippincott Company, 1928. Volume I. Thirty-eighth Series. Pp. x plus 307, with numerous illustrations and plates. Annual Subscription, Rs. 37-8. Available at Messrs. Butterworth and Co. (India), Ltd., Calcutta.

THIS is a quarterly of illustrated clinical lectures and specially prepared original articles, on Treatment, Medicine, Surgery, Neurology, Pædiatrics, Obstetrics,

Gynæcology, Orthopædics, Pathology, Dermatology, Ophthalmology, Otolaryngology, Rhinology, Laryngology, Hygiene and other topics of interest to students and practitioners by leading members of the medical profession throughout the world, edited by Henry W. Cattell, A.M., M.D., Philadelphia, U. S. A., with the collaboration of many well-known authors.

This volume contains about one hundred illustrations including some important ones relating to medical history of the period of the Renaissance. This will prove of immense value to advanced and post-graduate students as well as to practitioners, as they may get information on various important topics contained in the series of volumes compiled by the leading members of the profession of the world.

S. P. B.

RECENT ADVANCES IN CHEMISTRY IN RELATION TO MEDICAL PRACTICE.—By W. McKim Marriot, B.S., M.D. St. Louis: The C. V. Mosby Company, 1928. Pp. 141. Illustrated. Price, \$2.50 net.

THIS is a well got-up volume consisting of 138 pages divided into a series of six lectures. These lectures have been given primarily for the purpose of acquainting medical practitioners with the recent advances in chemistry that are applicable to medical practice. On taking up the book we rather expected to find a volume devoted to chemical formulae and technicalities but in this we were agreeably surprised and found instead a very practical exposition of the modern applications of the recent chemical advances that bear on the practice of medicine. The book as noted before, is divided up into a series of lectures commencing with one on fundamental considerations. This lecture on the whole is slightly disappointing though it must be admitted that it is an almost impossible subject to compress into one lecture, and at the same time hope to give a lucid account of atoms, molecules, ions, mass law, etc. Lecture No. 2 deals with acidosis and alkalosis and here the real value of the book is revealed as the subject is dealt with in an able and very practical manner. Lecture No. 3 is on the chemistry of the blood which is also dealt with simply and practically. Lectures No. 4 and 5 are concerned with food and metabolism beginning with the fundamental principles of diet and gradually leading on to the application of those principles to dietaries suitable in diseased conditions, propositions that the general practitioner must consider very carefully in his everyday work. Lecture No. 6, gives an account of the endocrines and the subject is dealt with in an eminently sensible manner.

The book can be thoroughly recommended to the general practitioner and even the specialist will find much to cogitate on. It also serves a very important function in bringing the fundamental facts of chemistry to the ken of the busy practitioner and of these facts he is often ignorant, though they are of the utmost importance in the practice of medicine.

T. C. B.

TROPICAL GYNÆCOLOGY. (CLINICAL LECTURES).—By Colonel V. B. Green-Armytage, M.D., F.R.C.P., I.M.S. Calcutta and Simla: Thacker, Spink and Co., 1928. Pp. xv plus 842, with 3 plates and over 100 photographic and other illustrations. Price, Rs. 20.

THIS little book, a companion volume to "Tropical Midwifery" by the same author, is in the form of eleven lectures on a variety of gynæcological subjects. Most of these have already appeared in print at various times.

In the words of the writer—a collection of "some of my own experiences and findings over a period of 18 years" it is not intended as a text-book of gynæcology or even of tropical gynæcology, and, as is inevitable in a book of this kind, it becomes in places a veritable hotch-potch of information, but it nevertheless contains much interesting material and many practical hints of value both in private practice and in gynæcological surgery.

To quote the text again "It is important that all teachers and professors of gynæcology and obstetrics in India should keep up to date" and many of Col. Green-Armytage's lectures although beyond the scope of the general practitioner, indicate the fields in which modern advances have been made, Vide *Lecture XI* on the low Cæsarian section of De Lee much advocated by the writer—the use of glucose and insulin in shock, *Lecture IV* on Sterility and the use of Rubin's insufflation test and Hobb's glycerine injection. *Lecture VII* on Prolapse is also particularly good and useful in a country where this condition is so common. *Lecture VI* on pelvic inflammation and *Lecture VIII* on vaginal hysterectomy may also be mentioned as containing much modern and useful information. *Lectures II, III, IX, X*, are in the form of notes on various subjects—*Lecture II*, on disorders of pregnancy, on prolapse, fistula and cancer—*Lecture III*, on disorders of menstruation—*Lecture IX*, on sterility, chronic metritis, prolapse, retroversion, and endocrinology—*Lecture X*, on hæmorrhagic ovarian cysts, fibroids, prolapse, varicocele of the broad ligament, pyelitis and menstrual disorders. Much of the material in these lectures is duplicated in other parts of the book but there are some useful hints and prescriptions.

In conclusion some mention must be made of the "hors d'œuvre" of the book, *Lecture I*, on obstetrics and gynæcology in the days of the Patriarchs—a very interesting chapter but one which should not be attacked without a Bible at hand for reference.

"Tropical Gynæcology," useful in size and material, will prove a useful addition to library and consulting room.

M. F.

Annual Reports.

ANNUAL REPORT ON THE WORKING OF THE G. I. P. RAILWAY MEDICAL DEPARTMENT, FOR THE YEAR 1927-1928. BY R. J. L. SLADEN, F.R.C.S. (ENG.), D.P.H., OFFICIATING PRINCIPAL MEDICAL AND HEALTH OFFICER, G. I. P. RAILWAY, BOMBAY.

THE figures contained in this report are based on an average subordinate staff population of 11,36,697. The total sick days' leave granted amounted to 5,92,508 while the average days lost per man per year (all classes) worked out at 8.84. The total cost of sickness for the year for all classes was Rs. 17,95,737. Analysing the figures still further it is found that 1,09,534 members of the staff were treated as out-patients and 2,139 as in-patients during the year.

Total deaths in out-door and in-door patients numbered 236 equivalent to 207.6 per 1,00,000 men employed. In addition to these figures, 48,184 members of the families of employees were treated as out-patients and 438 as in-patients. The total of deaths in this group was 113.

The G. I. P. Railway maintains no fewer than 8 District Hospitals containing 174 beds, in addition to 32 beds at various dispensaries. The number of beds works out at 1.81 per 1,000 of the staff and the average number of beds occupied in the District Hospitals per diem was 87.82.

A total of 2,770 operations (699 major and 2,071 minor) was performed at the District Hospitals during the year under review, an increase of 587 over the previous year. Periodical re-examinations of employees as regards visual acuity, colour perception, and hearing totalled 10,920 during the year ending 31st March, 1928, while corresponding examinations of recruits on appointment numbered 20,463 during the same period. In this connection Dr. Sladen remarks that:—"The class of the men applying for work in the shops do not appear to be drawn from very healthy stock. Out of 8,568 recruits, 1,397 failed to obtain the required standard, making a percentage failure of 16.30. The large number of failures was on account of defective vision.

Speaking generally this class of workmen live outside railway lands where the advantages of sanitation, well constructed and ventilated buildings obtained by the running staff are not available.

A feature which is coming to light in connection with re-examination of staff is the material benefit to workmen by prescribing suitable glasses for their work.

Defects in visual acuity are often not appreciated by the workers. They come on gradually and would be the reason for much inefficient work, and often would not be remedied in the absence of periodical re-examinations.

During the year ending 31st March, 1928, 239 prescriptions for spectacles have been issued from this office and far many more have been given by District Surgeons....."

Statistical Notes on certain special diseases.

(a) *Malaria*.—The prevalence of malaria for the system taken as a whole rises in May, with extreme uniformity to a maximum in October, falling thereafter gradually till March with a very insignificant rise in February.

Anti-malarial measures were maintained throughout the year at their former level. The Principal Medical and Health Officer attended joint conferences with various local bodies in the Island of Bombay including the Corporation, the military authorities, and the department is now co-operating with the Officer-in-charge Malarial Survey appointed by Government, for devising and co-ordinating anti-malarial measures in the city of Bombay.

Anti-malarial operations were carried out throughout the year such as filling of low-lying lands, improving drainage, destruction and prevention of breeding of mosquitoes, etc.

Attention has been drawn to the importance of accurate diagnosis and better records of cases of malaria and it is hoped that much useful information will be available in the course of the year. Efforts are being made to estimate more accurately the morbidity-rate from malaria and the number of working days lost through this disease, per employee per year, for the various grades and departments.

(b) *Influenza*.—Among staff, influenza of a generally mild type was moderately widely distributed: 7 sections furnished no returns.

For the line taken as a whole the maximum incidence was in March (247 cases); the minimum in December (123 cases); the total recorded cases 2,050, the average monthly return 170.83. Epidemic characteristics were wanting.

Amongst the families of staff the returns total 558 for the year, the maximum incidence was in March (67 cases), the minimum in February (22 cases), the average per month 46.5. Ten sections recorded no cases.

Examination of the individual sectional returns which in general run parallel with those for staff suggests that the bulk of all cases, presumably on account of the prevalently mild type of infection, escaped registration and that accordingly detailed analysis of the distribution is impossible.

(c) *Cholera*.—The total number of cases of cholera which occurred on the line was 114, of these 49 were among the staff and 65 in the families.

(d) *Small-pox*.—The period of maximal incidence was in May and of minimal incidence in September—November. The total number of cases returned as treated was for staff 156, for families of staff 271. The total number of deaths returned as due to small-pox was 19, equivalent to 4.4 per cent. of the reported cases amongst employees and members of families.

(e) *Plague*.—The staff and their families suffered lightly from plague during the year. Jubbulpore alone returning double figures—the total reported cases amounted in all to 65 with 14 deaths. 21 cases occurred amongst employees and 44 amongst their families.

(f) *Veneral Disease*.—The total return of venereal Diseases treated among employees was 799 or, to very near approximation, 0.7 per cent. of the average staff employed.

For various reasons the returns cannot be regarded as adequately representative of the prevalence of venereal disease in the community.

Returns of Accidents.

The accidents reported, as occurring to staff and public in the year aggregated to 1,891, of which 1,354 occurred among staff, 241 among passengers and 296 to outsiders, such as trespassers, etc. 220 resulted in the death of the injured. The incidence of accidents amongst staff was accordingly 1.19 per cent. and that of the fatal accidents about 0.036 per cent.

In the year under review there have been 197 more cases reported than in the previous year, but the number of deaths has been 41 less.

In addition to these cases, 20,660 cases of injuries (general and local) have been treated as reported in the monthly hospital and dispensary returns, being an excess of 1,032 over the previous year. Some of these injuries are indirectly connected with duty.

Greater attention is now being paid to minimising the number of days lost by an employee through injuries—one of the chief duties of the medical departments of railways being the efficient treatment of injuries.

The important factors in lessening injuries and their effects may be stated as—

- (1) Safety First movement.
- (2) Rendering of prompt and efficient First Aid.
- (3) Prompt and skilful professional treatment.

Vaccination and other prophylactic inoculations.

(a) *Anti-rabic treatment*. The prophylactic treatment of staff and the families of staff bitten by rabid animals continued to be carried out at two centres on the railway—at Byculla where treatment was available throughout the year, 319 cases were treated with no deaths: at Jhansi where patients were received for treatment from November to February, 8 cases were treated with no deaths.

(b) *Vaccination returns* showed a total of 1,576 performed, viz.:—

	1927-28.	1926-27.
(a) Primary	1,013	1,002
(b) Secondary	563	794
(c) Anti-plague	1,026	1,571
(d) Anti-cholera	526	..
(e) Anti-enteric	18	19

Clinical Pathological Laboratory Returns, etc.

The total number of examinations of all sorts conducted in the Clinical Laboratories attached to District Hospitals at Igatpuri, Bhusaval, Jhansi, Ajni, Jubbulpore and Sholapur, amounted to 6,249 during the year. The development of work was satisfactory though capable of much further profitable extension in the future. The laboratories attached to Igatpuri, Bhusaval, Jhansi, Jubbulpore and Sholapur Hospitals, furnish returns of interest and of value. Good work was done in the investigation of clinical malaria. The total expenditure during the year on outside assistance to the laboratory diagnosis of sickness amongst staff was extremely small like last year.

Training in First Aid.

The statement of the year's gross results show that 74 classes were held and that 744 employees attended for instruction, of whom 490 passed in First Aid, 11 for the Voucher, 6 for the Medallion and 1 for the Label. The total number successfully trained up to the end of the period under review was 2,076 equivalent to about 1.83 per cent. of the average total staff.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY FOR 1927. BOMBAY: THE TIMES PRESS. 1928.

THE salient features of the above report may be summarised as follows:—

The number of live-births registered during the year was 21,685, being 617 more than in 1926, 775 more than

the annual average in the quinquennium (1922-1926) and 933 more than that for the last decennium (1917-1926).

The deaths registered during the year numbered 27,633. The death-rate or number of deaths in the year per 1,000 of the estimated population was 21 and was lower than the rate for any year, since death-rates were first calculated in 1872.

Deaths from Plague numbered 207 during the year, as against 56 in 1926 and 520 the average of the preceding quinquennium (1922-1926).

Small-pox caused 842 deaths as against 480 in 1926 and 560 the average in the last decennium (1917-1926). Small-pox was epidemic for 15 weeks from 27th February, 1927.

Cholera was registered as the cause of 82 deaths, as against 5 in 1926 and 1,062 the average of the ten years 1917-1926.

Influenza caused 79 deaths as against 90 in 1926 and 999 the mean of the last ten years (1917-1926).

The deaths from diseases of the Respiratory System numbered 9,949 as against 11,901 in 1926 and 16,567 the average for the preceding decennium.

Tuberculosis accounted for 1,748 deaths as against 1,844 the mean of the ten years 1917-1926.

The number of deaths from Malaria was 365 and from Ague and Remittent Fever 1,633 as against 635 and 2,004 deaths respectively in 1926. The average number of deaths for the last five years 1922-1926 from Malaria was 518 and from Ague and Remittent Fever 2,483.

The deaths among infants under one year of age numbered 6,857 as against 8,200 in 1926 and 10,032 the average for the preceding decennium (1917-1926). The rate of infant deaths per 1,000 registered was 316, being the lowest on record since rates were first cast in 1874 for infants under the age of 12 months.

Compared with the decennial averages (1917-1926), the total number of deaths shows a decrease of 16,150, the principal decreases in the mortality being 527 under Plague, 128 under Measles, 980 under Cholera, 920 under Influenza, 52 under Malaria, 1,484 under Ague and Remittent Fever, 96 under Tuberculosis, 2,051 under Diarrhoea, Enteritis and Dysentery and 6,618 under diseases of the Respiratory System.

It is particularly noteworthy that the general death-rate and the mortality among infants under one year were the lowest on record.

Excluding 1,780 still-born children, the number of births registered during the year was 21,685 and was more by 617 than in 1926 and by 933 than the annual mean number of births registered in the ten years, 1917-1926.

The birth-rate calculated on the estimated population for 1927 was equivalent to 16.7 births per 1,000. Calculated on the Census population for 1921, the birth-rate was 18.4.

Of the children whose births were registered, 10,998 were males and 10,687 females, the proportion of males to females being 1,029 to 1,000.

The low birth-rate recorded year by year for the city is probably by no means a fair measure of the true fertility of the population. It is in part due to the custom whereby married women leave the city for their confinements and register their children in the mofussil districts where they are born.

The number of infants certified as still-born was 1,780 as against 1,676 in 1926 and the decennial average 1,900. Still-births are excluded in this report from all figures relating to deaths and to births not expressly defined as still-births.

The total number of deaths registered from all causes during the year was 27,633 being 4,358 less than in 1926. It was 7,965 less than the average annual mortality of 1922-1926 and 16,150 less than the average annual mortality of the preceding 10 years (1917-1926). The death-rate per 1,000 persons living was 21 and was lower than that for any year since 1872. The death-rate (like the birth-rate) is invariably high amongst the poorer classes; and as an unduly large proportion of the population of the city belongs to the most poorly paid sections of society, the general death-rate is raised by that of the unusually large proportion of the very poor. The

Census of 1921 showed that 66 per cent. of the population live in one-room tenements.

Of the total number of 27,633 deaths in the year, 15,238 were among males and 12,395 among females. The larger number of deaths among males is due to the preponderance of males who form nearly two-thirds of the population, the actual death-rate being higher among females. Thus the male death-rate was 18 and the female death-rate 27 as against 21 and 33 respectively in 1926.

Diseases of the Respiratory System caused, as usual, a higher death-rate than any other group. Congenital Debility and Diseases of Early Infancy constituted the next most fatal group giving a death-rate of 2 per 1,000 persons living. The group coming next on the list for the year under report with a death-rate of 1.4 comprises the deaths attributed to Malaria, Ague and Remittent Fever.

Two rises in the mortality occurred, one in March due in part to deaths from Plague and Small-pox, and one in August in the rains due largely to deaths from Malaria, Ague and Remittent Fever.

The number of deaths among infants under one year of age was 6,857 being 1,343 less than in 1926, and 3,715 less than the annual average in the ten years, 1917-1926.

The infant mortality rate expressed as the number of deaths in infants per 1,000 registered births was 316 as compared with a rate of 389 in 1926 and of 483, the annual average in the decennium (1917-1926).

Of the total deaths 4,631 occurred among infants born in Bombay, and 2,226 in infants born elsewhere.

5,224 or nearly 76 per cent. of the total deaths in infants were due to diseases of the Respiratory System. Infantile Debility and Premature Birth against 77 per cent. (6,347 deaths) in 1926. Diarrhoea and Enteritis caused 333 deaths, Malaria, Ague and Remittent Fevers 115 deaths and Convulsions 688 deaths. The deaths from Small-pox and Measles numbered 151 and 32 respectively.

The high rates recorded suggest the presence in Bombay of some adverse factor in addition to the poverty and ignorance which are chiefly responsible for high rates in western countries. The added factor affecting all classes is probably malaria; another factor which can hardly fail to enhance the infant mortality among the more ignorant portions of the population is the practice of soothing babies by the administration of opium.

Syphilis, as recently emphasized by the delegates of the British Social Hygiene Council, contributes to the death-roll but whether to a greater extent than in other cities it is not possible to say when an overwhelming majority of the total deaths under one year are not certified by medical practitioners.

The work which is being done in Bombay for the reduction of infant mortality may be described under the following heads:—

(i) Visits by the Municipal District Nurses for the purpose of getting into touch with prospective mothers and for discovering cases of sickness especially among women and children and unvaccinated children; for inquiry into the condition of new-born infants; and for giving instruction by homely talks as to the care and rearing of children.

(ii) Attendance on confinements.

(iii) Provision of necessaries and comforts during the lying-in period.

(iv) Maternity Homes.

(v) Infant Milk Depôts.

(vi) Infant Welfare Centres.

Notification of Infectious Diseases.—The total number of cases of infectious disease registered during the year was 3,941. Under section 421 of the Municipal Act, 608 were notified by medical practitioners, as against 388 in 1926. Three cases were notified by Hakims and Vaidyas, who are not required by law to notify. 3,330 cases or 85 per cent. of the total number were found and reported by the District Registrars.

Plague.—Plague did not assume epidemic proportions at any time during the year. The number of Plague attacks was 223 against 63 in 1926. The disease caused 207 deaths in the year against 56 in 1926 and 734, the average for 1917-1926. The mortality among reported

cases was 93 per cent. as against 89 in the previous year.

The death-rate from Plague during the year was 0.16. *Plague Measures.*—The usual preventive and precautionary measures, namely, (i) Inoculation, (ii) Rat Destruction, (iii) Evacuation and (iv) Disinfection, were continued during the year.

(i) *Inoculation.*—During the year, 100 inoculations against Plague were performed at the Haffkine Institute and 1,208 by the Municipal Medical Inspectors.

(ii) *Rat Destruction.*—The total number of rats collected and destroyed during the year was 592,936 against 579,806 in 1926. Of the 592,936 rats collected and sent to the Parel Laboratory, 261,766 were examined and 1,421 were found infected, giving a ratio of 0.54 infected rats per 100 rats examined as compared with a ratio of 0.45 in 1926.

The percentage of infected rats rose from 0.28 in January to 1.38 in May and then declined gradually to 0.19 in November.

(iii) *Evacuation.*—For the reception of contacts from infected dwellings, semi-permanent Health Camps at Koli Lane (Colaba), Suklaji Street, Tardeo, Arthur Road, Chinchpoogli (at the junction of DeLisle Road and Arthur Road) and Mahim Station were maintained.

(iv) *Disinfection.*—For the destruction of fleas, all rooms in which cases of Plague either in rats or in man had occurred were disinfested with Pesterine. Infested bedding is disinfected by steam.

Small-pox.—Small-pox was prevalent in the city throughout the year and caused 842 deaths against 480 in 1926 and 560, the average for the preceding ten years (1917-1926). The number of attacks from Small-pox registered during the year was 1,407 (including 51 imported cases) against 805 attacks in 1926.

The death-rate from Small-pox during the year was 0.64 as against 0.37 in 1926 and 0.4, the average during the preceding decennium.

As usual, the death-rate from Small-pox attained its maximum between March and May and fell to a low figure in the subsequent months of the year.

One hundred and fifty-one deaths from Small-pox occurred in children under one year of age and 235 in children aged 1-5 years. Of the total deaths, 386 or 46 per cent. thus occurred in the first five years of life against 49 per cent. in 1926.

Vaccination.—There are 20 Vaccination Stations in the city. Three stations are open in the morning on every Monday, Wednesday, Friday and Saturday and two on every morning during the rest of the week. The station at Princess Street is open every Sunday and Wednesday morning and when Small-pox is prevalent in the city, during the afternoon hours on working days.

The total number of primary vaccinations and of re-vaccinations performed during the year was 20,374 and 29,196 respectively as against 18,615 and 16,888 in 1926.

The proportion of primary vaccinations (13,900) in children under one year of age to the total number of births (21,665) registered during the year was 64 per cent.

Of the 151 infants under one year of age who died of Small-pox during the year, 126 were not vaccinated and 3 were vaccinated during the incubation period. In the remaining 22 cases, the vaccinal condition was not ascertained.

Cholera.—There were 151 attacks and 82 deaths from Cholera during the year as against 5 attacks and 5 deaths in 1926.

The outbreak began in the first week of July, reached its maximum in the week ending 30th July and ended from the week ending 10th September.

Posters recommending the precautions to be taken including inoculations were affixed in various parts of the city. Inoculation stations through the kindness of the Medical Officers in charge were opened at the principal Hospitals in the City in addition to the 13 Stations provided at the Municipal Dispensaries. The total inoculations performed numbered 8,966.

In view of the magnitude of the epidemics of Cholera which occurred at this time in so many parts of India and the Bombay Presidency, the city may be regarded

as fortunate in having escaped with an outbreak which did not in any one week produce more than 25 deaths.

Influenza.—The number of deaths registered as due to Influenza during the year was 79 and was 920 less than the average of the last ten years (1917-1926).

Tuberculosis.—The number of deaths from Tuberculosis was 1,748 and the death-rate 1.34 per 1,000 of the population. Of these, 1,577 were due to Phthisis (Pulmonary Tuberculosis) and 171 to other Tuberculous Diseases.

There were 859 deaths among males and 889 among females. The disease caused a greater number of deaths among persons in the age-group of 20 to 40 years than in any other age period.

There are two dispensaries for out-patients suffering from Tuberculosis—one at the Sanitary Institute, Princess Street, and the other in Foras Road and the Turner Sanatorium containing 32 beds for in-patients on Bhoiwada Hill, Parel.

Each dispensary is in charge of a Medical Officer and three nurses are employed for visiting the patients who attend, reporting on the home conditions and seeing that they follow in their homes the advice which they receive. Of the three nurses, two are employed at Princess Street and one at Foras Road.

During the year under report the total number of Tuberculous patients treated at the two Dispensaries was 1,406; the number treated in 1926 was 1,240.

Of the 1,406 cases, 1,211 were cases of Pulmonary tuberculosis and 195 cases of Surgical Tuberculosis. The total attendances numbered 11,573.

The Medical Officers and Nurses paid 3,046 domiciliary visits to see patients too ill to attend the Dispensary.

In the Turner Municipal Sanatorium at Bhoiwada, 32 beds, 18 for males and 14 for females, are provided for patients in the early stages of consumption. The use made of the Sanatorium and the results are shown in the following tabular statements:—

Number remaining over from previous year ..	23	
Number of new admissions ..	108	
Number remaining at the end of the year ..	27	
<i>Stage of the Disease.</i>	<i>Males.</i>	<i>Females.</i>
Stage I (Early) ..	32	20
Stage II (Moderately advanced) ..	17	15
Stage III (Advanced) ..	14	10
TOTAL ..	63	45

Malaria was registered as the cause of 365 deaths, 1,633 deaths were registered as due to Ague and Remittent Fevers. Under the last two heads a number of deaths are no doubt included which were due not to Malaria but to one or other of the various diseases such as Typhoid, Tuberculosis and Influenza in which fever may be a prominent symptom.

The numbers of deaths from Malaria and from Ague and Remittent Fevers in 1927 were 365 and 1,633 and the annual averages in the ten years 1917-1926, were 417 and 3,117 respectively.

Measures for gauging the incidence of Malaria were continued during the year.

The inspection of houses and the destruction of larvæ were carried on on a systematic plan. The sections of the Wards were further sub-divided and each Overseer was given an area which he could cover within a week. The breeding places detected were immediately dealt with. Slight defects in the permanent breeding places were attended to by the Staff and action was taken against the owner only when the repairs were expensive and costly.

Children of the poorer classes were examined for enlargement of the spleen in dwelling houses and in Charitable Institutions. Out of 5,342 children so examined 403 were found to have enlarged spleen. The spleen rate for the whole city was 7.54 against 7.97 in 1926 and 7.60 in 1925.

The total number of wells in the city should have been 3,003 according to last year's report. 148 wells were, however, discovered during the year. A few of

these were new wells sunk without permission and were subsequently filled in. One well was permitted to be sunk.

Cisterns.—Defective non-mosquito-proof manhole covers were, in response to letters or notices, replaced by the new hinged iron standard caps under lock and key in 766 cases during the year. The total number of cisterns in the city is 25,846.

Tanks.—(1) Mill tanks. There are 88 mills in the city with 117 mill tanks. These tanks are always found to constitute a danger to Public Health by reason of their breeding mosquitoes frequently. The matter was taken up by the Malaria Advisory Committee appointed by Government for devising and co-ordinating anti-malarial measures in the city of Bombay. The Committee recommended that attention should be concentrated on the filling in of the tanks at once or gradually every year. But in view of the present depressed state of the industry, they recommended a scheme of oiling, pending the filling in of the tanks at a cost varying from Rs. 55 to 95 per mensem according to the size of tank. The scheme is to pour on the surface of the water one gallon of a mixture of three gallons of residual oil, two gallons of kerosine oil and two ounces of castor oil for every 25 linear feet if the tank is found breeding.

As an experimental measure the owners of the mills worked with electricity (and where the mill tanks were found breeding frequently) were advised to participate in the scheme which was brought into force from September 1927.

The owners are given the option of supplying their own oil, when Rs. 15 per mensem are charged for supervision and treatment of the tank when necessary.

Eleven mills have joined the scheme during the year.

The mill tanks were regularly examined and treated with larvicides if found necessary. 54 tanks were found breeding at some time or other during the year.

Quinine and Cinchona.—66 lbs of quinine and 83 lbs of Cinchona Fehrigue were supplied to patients and others free of charge through the 13 Municipal Dispensaries and other Municipal Agencies and at the Municipal Maternity and Infectious Diseases Hospitals. 1 lb. of quinine and 22 lbs. of Cinchona were distributed in the form of tablets numbering 46,106 in all. The remainder was issued in the form of powder.

Out of 46,106 tablets 9,138 tablets were distributed by Municipal Inspectors and others partly for treatment and partly for prophylactic purposes. The remainder of the supply of tablets and powder was administered in Medical Institutions to patients suffering or suspected to be suffering from malaria.

Venereal Diseases.—The number of deaths ascribed to Venereal Diseases during the year was 26 against 41 in 1926. Of the 26 deaths, 20 were due to Syphilis.

Early in the year 1918, a League for Combating Venereal Diseases was established in Bombay under voluntary management, with the Head Office, Information Bureau and an Outdoor Dispensary at No. 66, Lamington Road. The management was taken over by the Bombay Municipality from 1st April, 1925. At the Information Bureau, information and advice are given to the public and educational literature in English and the Vernaculars is distributed. Outdoor anti-venereal propaganda work is also carried out. The Dispensary is well equipped with all the necessities for the free diagnosis and treatment of Venereal Diseases by modern methods. The Staff of the Dispensary consists of a Medical Officer in charge, a Lady Physician, a Nurse, and Dispensary and Laboratory Assistants.

A post-graduate course of training for qualified medical practitioners is held three times a year. It is conducted by the Medical Officer in charge at the Dispensary, where provision is made for laboratory instruction and ample facilities are available for clinical work. During 1927, eleven post-graduate students have received training and completed their courses.

During the year ending 31st December, 1927, the number of patients registered in the Dispensary was 2,844 (2,547 males and 297 females).

During the year under report 677 injections of Nov-arsenobillon were given and 611 Wassermann Tests

were made, besides a very large number of other injections and tests.

Out of the 2,844 cases registered during the year, 253 ceased attending before the diagnosis was completed and 286 (234 males and 52 females) were diagnosed as non-venereal. The remaining 2,305 with the addition of 392 cases carried over from last year give a total of 2,697 (2,416 males and 281 females) venereal cases which are classified as follows:—

	Males.	Females.	Total.
Syphilis ..	714	78	792
Gonorrhœa ..	1,389	143	1,532
Soft Chancre ..	313	60	373
TOTAL ..	2,416	281	2,697

Municipal Dispensaries.—The thirteen Municipal Dispensaries were open throughout the year to administer, as in the past, free medical relief to the sick poor of the city.

The number of new cases treated at the dispensaries during the year was 68,887 (47,888 males and 20,999 females) as against 71,921 in 1926. The total attendances numbered 166,991 as against 192,626 in 1926. These figures include 888 visits by the Dispensary Medical Officers to patients in their homes.

Sanitary State of the City.—The principal causes of the insanitary conditions which maintain the death-rate at a high level even in non-epidemic periods are the insufficiency of the sewers the continuance of the basket privy system of conservancy, the density of houses and persons per acre and the overcrowding of persons in rooms and tenements.

With the completion of the new Tansa pine line, the city as a whole is now provided with an adequate and constant supply of water from Tansa lake. The whole supply has been chlorinated throughout the year. No provision of any kind is made for filtration.

NOTES ON THE ANNUAL STATEMENTS OF THE HOSPITALS AND DISPENSARIES IN THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1927. BY COL. J. NORMAN WALKER, M.R.C.P. (LOND.), D.T.M. & H. (CAMB), I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, CENTRAL PROVINCES. GOVERNMENT PRESS, NAGPUR, 1928. PRICE, RS. 6-7.

THERE were 314 hospitals and dispensaries at the close of 1926. During the year 1927, 10 dispensaries were opened and four closed leaving 320 institutions at work on 31st December, 1927. The following dispensaries were closed; Ghogra Irrigation dispensary, two mission dispensaries at Morpha and Champa and one railway dispensary at Mophani Collieries in the Narsinghpur district. During the year no dispensaries were transferred to Local Bodies but one cheap plan dispensary was opened at Babai under the management of the District Council, Hoshangabad. Another at Sandia in Sohagpur *taluk* is to be opened during the year 1928 by the same District Council. Two dispensaries, one at Karanja in Wardha district and one at Shahpur in Betul district, were opened during the year under the management of the Dispensary Fund Committee and under the direct supervision of the Civil Surgeon. The re-opening of the dispensary at Garha under the management of the Jubbulpore Municipal Committee has been approved by Government and it will be re-opened shortly.

A cheap plan dispensary at Bamni has been opened by the District Council, Mandla, this year. Government's sanction to the opening of five cheap plan dispensaries under the management of the District Council Buldana, at Tamgaon, Bori-Adgaon Lonar, Janephal and Amrapur has been received and these have begun work. Provision also exists in the next year's budget for 1928-29 for opening additional cheap plan dispensaries in Berar. The policy of Government in this matter is that local bodies should take the initiative and their applications to found cheap plan dispensaries are sympathetically considered and financial assistance given.

Several local bodies are taking advantage of the scheme but it is noticed that the demand is greater from Berar than from the Central Provinces districts. The scheme for subsidizing qualified private practitioners to settle in villages, at a distance of not less than 8 miles from existing dispensaries, has been approved by Government but could not be given effect to during the year under report as funds could not be provided. The request for Rs. 12,000 has been repeated in the current year's budget and passed by the Legislative Council. Progress will be made with the scheme in 1928-29. A great advance has been made in the matter of medical treatment for women by women doctors. Two special women's hospitals were constructed in 1927, one at Chhindwara was opened during the year and the other (Lady Butler Hospital) at Khandwa was opened in January 1928, by Lady Butler in the presence of His Excellency the Governor. Government sanctioned the appointment of seven female Assistant Surgeons during the year and they have been attached to the Main Hospitals at Betul, Damoh, Bhandara, Balaghat, Seoni, Chanda and Bilaspur, where special facilities for separate treatment of men and women either have or are being made. The places selected are those where no special women's hospital exists. Provision for five more Assistant Surgeons has been made in the budget for 1928-29. In addition to the women Assistant Surgeons there are nine women Assistant Medical Officers attached to certain dispensaries and that number is being increased by two.

The total number of patients treated was 2,195,902 against 2,108,152 in 1926 or an increase of 87,750. The increase is noted in all districts with the exception of Seoni, Balaghat, Narsinghpur, Saugor, Damoh and Raipur.

The number of in-door patients increased from 23,755 in 1926 to 25,326 in 1927.

The number of beds available rose from 1,806 to 1,842 during the year due to an increase of 15 beds at the Akola Dufferin Hospital and the opening of the new Dufferin Hospital at Chhindwara with 20 beds. There were 1,066 deaths against 1,033 in 1926, the ratio of deaths to total treated being 4.21 per cent. against 4.35 in the previous year.

The number of out-door patients treated rose from 2,084,397 in 1926 to 2,170,576 in 1927.

The principal diseases for which relief was sought at all classes of hospitals and dispensaries are in numerical order as follows:—

Diseases of the skin, diseases of the digestive system, fevers, diseases of the eye, diseases of the respiratory system (except pneumonia and pulmonary tuberculosis) and diseases of the ear. 482 patients were treated for small-pox against 591 in the previous year. Of the 482 patients treated during the year 1927, 195 were vaccinated, 137 were unprotected and the vaccinal condition of the remainder was not recorded.

Of the total number of (2,607,948) patients treated in all classes of hospitals and dispensaries, 52.21 per cent. were male adults, 16.61 per cent. female adults, 18.39 per cent. boys and 12.79 per cent. girls, as compared with 51.74, 16.66, 18.61 and 12.99 per cent., respectively, in the year 1926.

The total number of cases of venereal diseases treated rose from 23,312 in 1926 to 27,616 in 1927. These figures do not, however, indicate the real state of the prevalence of these diseases as for obvious reasons a large percentage of those affected do not attend public hospitals for relief. There is, however, an increase of 4,304 over last year's figures. This would seem to indicate a more general appreciation of the special measures now being taken for the relief of venereal disease. Among the anti-venereal measures recommended, the Local Government has recently approved of Civil Surgeons giving instructional lectures to students in the Matriculation classes in certain selected districts. A provision of Rs. 8,000 has also been sanctioned in the budget for 1928-29 on account of grants to main hospitals for special treatment which will be given free of charge to poor patients.

The number of surgical operations rose from 71,436 in 1926 to 79,352 during the year, the number of selected

operations performed during the year is 5,353, of which 759 were for cataract.

There are now five anti-rabic centres in this province, that is, one in each division, the centre in Berar being at Akola and all others at divisional headquarters. 1,045 patients were treated at these five centres. Reports from these centres have been submitted separately to Government.

There is an increase of 358 patients under the heading leprosy during the year. Arrangements have been made for the treatment of leprosy cases at all the main hospitals in the province. Government grants have been given to meet the cost of building out-door dispensaries for leprosy cases at the main hospitals at Yeotmal, Buldana, Bhandara, Khandwa, Raipur, Bilaspur and Drug. A sum of Rs. 4,352 will also be given to the Mayo Hospital, Nagpur, for the same purpose. Grants of Rs. 500 each have also been given to these eight hospitals and Rs. 300 each to other main hospitals for special drugs, etc., for the newest treatment of leprosy cases. A grant of Rs. 250 each was also paid for equipment at the above eight main hospitals by the Provincial Committee, Central Provinces, of the British Empire Leprosy Relief Association. Seven Assistant Surgeons and 50 Assistant Medical Officers have been trained in the modern methods of diagnosis and treatment of leprosy under Dr. Muir at the School of Tropical Medicine, Calcutta. A leprosy survey in the Chhattisgarh division has just been undertaken and will include many centres for special treatment.

The training of Nurses at the Mayo Hospital has been reorganized, six probationers are admitted yearly for a training of three complete years. From 1930 six qualified nurses should complete their training yearly and it is believed that their work will be of great value to the province. Qualified nurses are now to be employed at certain hospitals where the number of in-patients is large. These nurses will have half their pay paid by Government and a proportion of their house rent will also be paid by Government until free quarters are available.

Health propaganda work is done by Assistant Medical Officers in charge of all outlying dispensaries in their own dispensary towns with the help of charts and pamphlets. Propaganda work in adjoining villages is also being tried in some districts. The results are variable. The Civil Surgeon, Raipur, suggests that to make this work more attractive and instructive a supply of magic lanterns and slides prepared in a simple manner is essential. The Civil Surgeon, Amraoti, says that this is not popular and except where instruction is given in schools he does not consider it to have any value.

Colonel K. V. Kukday, C.I.E., I.M.S., was in charge of the office of the Inspector-General of Civil Hospitals till 14th September, 1927, when he proceeded on leave for six months preparatory to retirement. Colonel J. Norman Walker, I.M.S., took charge from him on that date.

MADRAS GENERAL HOSPITAL (1664-1928). COMMEMORATIVE BOOKLET. SUPDT., GOVERNMENT PRESS, MADRAS. PRICE, RS. 2.

THE first step in the remodelling scheme of the Madras General Hospital was taken on 23rd August, 1928 when His Excellency Lord Goschen the Governor of Madras, laid the foundation-stone of the new out-patients' block. To commemorate this event a beautifully illustrated booklet has been issued by the Madras Hospital authorities. The Hospital had its origin in the very earliest days of British administration in India and as one might imagine it was designed primarily for the use of the small handful of troops quartered at Fort St. George. It is obvious that in those far-off days the invalid soldier had to fend for himself very largely, hence one of the objects of the Hospital was to ensure that "people be appointed to look after them" (i.e., the sick) "and to see that nothing comes into them, neither of meat nor drink, but what the Doctor alloweth." Some idea of the ups and downs of the Hospital may be gathered when we read that between 1664 (the approximate date of its foundation) and 1753

it had changed its situation five times and that it had to change places four times more before it moved into its present tenement: at least once during its long career the Hospital has been nearly demolished by a cyclone.

From its very humble beginnings over 250 years ago the Hospital has grown until now it has accommodation for 540 in-patients: the remodelled Hospital, designed to contain 650 beds and fully equipped for medical and scientific investigation will challenge comparison with any other institution of the kind in the East.

The commemorative booklet is embellished with a series of excellent photographs and an architect's plan: it is being sold at Rs. 2 and profits will be devoted to the Emergency Fund of the General Hospital.

REPORT OF THE CHEMICAL EXAMINER TO GOVERNMENT, PUNJAB, FOR THE YEAR 1927. GOVERNMENT PRINTING PRESS, LAHORE. PUNJAB. PRICE, RE. 0-10-0 OR 1s.

THE salient features in this report may be summarised as follows:—

In the year under report the total number of cases of all kinds examined amounted to 2,557 comprising 7,046 articles as compared with 1,998 cases and 5,967 articles during the year 1926.

The figures as compared with those of the previous year show an increase of 559 cases and 1,079 articles received for examination.

Of 659 human poisoning cases, including 11 cases of abortion, 344 were fatal. Of 55 cattle poisoning cases, 50 were fatal. Of 888 stain cases, 509 were cases of murder or hurt by violence, 262 were of rape, 113 were of unnatural offences under section 377. Indian Penal Code, and the remaining 4 were of miscellaneous stains. Forty-three cases were received for opinion as to identification of human hairs, bones, etc.

Of 1,832 articles examined under the head "General analysis," 1,689 were sent by the civil and 143 by the military departments.

The percentage of detection in human fatal cases for 1927 was 70.27 as against 69.74 for the year 1926.

In 206 human poisoning cases no indication of the poison suspected was given. In 23 cases the indication given was misleading, i.e., poison other than that indicated was found. In one case no history of the case and in one case only the contents of the lower portion of the ileum was sent; stomach, liver, kidney, etc., were omitted, hence no poison was detected. In 4 cases of opium poisoning the stomach was washed with potassium permanganate solution which interfered with the tests for opium.

The largest number of fatal human poisoning cases in the Punjab originated from Amritsar (36), Lahore (25) and Sialkot (14) cases, Delhi Province and Patiala State 17 and 11 cases, respectively.

Stain Cases.—Two thousand and thirty-eight articles were received and examined during the year under report. The results were as follows:—

	Articles.
Blood was detected in	1,190
Semen was detected in	169
Blood and semen in	65
Gonococci in	5
Vaginal epithelial cells	2
Gonococci and pus cells	2
Kidney shaped diplococci	2
Semen and faecal matter	2
Pus cells	1
Blood and faecal matter	1
Pus cells and blood	1
Excreta	1
Blood not confirmed	4
Insufficient for identification	5
Sulphuric acid	2
Kerosene oil	2
TOTAL	1,454
Articles on which no stains were detected	584
GRAND TOTAL	2,038

In one article hairs were found to be those of a horse and not of human origin as was suspected.

Out of 509 blood cases, 446, comprising 1,054 articles, were sent to the Imperial Serologist during the year from stations in the Punjab for identification of the source of blood. Blood was detected in 1,052.

General Analysis.—During the year 1,832 miscellaneous articles were examined as against 1,458 in the previous year. This shows an increase of 374 articles.

This increase is due mainly to excise work, which is being performed from 1st April, 1927. Prior to that date this work was carried out in the Excise and Customs Laboratory, Calcutta.

Out of 45 Distillery samples, one was found to contain furfural.

Out of 22 samples of Lahan received, one contained no Lahan. Four samples of still were found quite satisfactory to produce good spirit.

Both of 2 samples of beer were found to be of good quality.

There were 8 samples of beer, wine and country spirit. All of them were found to be fit for human consumption.

Ten samples of illicit liquor were received from Nabha State.

Of 218 samples of cocaine, 147 were found to be pure.

Of 38 samples of charas, 24 were found fit for human consumption.

Of 354 samples of water, 247 were sent by the Railway Department, among which 127 samples were found fit for loco and drinking use; 16 were found fit only for loco use. The remaining 104 samples were found unfit for either purpose.

One hundred and twenty-seven samples of drugs were sent by the Medical Store Depôt, Lahore Cantonment. Out of these, 61 samples were of chloroform and 6 of sulphuric acid and the remaining 60 samples were of different kinds.

Twenty-seven samples of ghee were examined of which only 12 were found fit for human consumption.

Interesting side-lights on the poisons commonly used in the Punjab together with brief notes on some fatal cases of poisoning are embodied in the appendix to the report.

The commonest poisons used in the Punjab are opium, arsenic, dhatura and mercury. Opium heads the list and is mostly used for suicidal purposes because it can be very easily procured from the bazar and is reputed to be a comparatively peaceful means of self-destruction. A few homicidal cases are also recorded and these as a rule are children or invalids. The typical odour and taste of opium preclude its use as a homicidal poison amongst healthy grown-up people.

Arsenic comes next on the list. Unlike opium, arsenic is used with homicidal intent. It is tasteless, can be easily procured and is fatal in minute doses. It is therefore the favourite poison of the murderer. White and yellow arsenic are commonly used.

Dhatura.—This is almost always used to commit robbery. Victims are generally found in a state of unconsciousness in trains, inns and sometimes in public thoroughfares. Ground seeds are as a rule given mixed with sweets and food. Death is uncommon. A few cases of accidental dhatura poisoning are recorded.

Rarer poisons detected in fatal cases were strychnine, cocaine, chloral hydrate, copper sulphate, powdered glass and carbolic acid. Cocaine cases are usually accidental, due to overdose of the drug. Strychnine is more often used with suicidal intent and this together with other less common poisons is used by people, such as compounders, Hakims, etc., who have some knowledge of medicines.

Sulphuretted hydrogen gas.—Two men went down a well and started work. After a short time both became unconscious and died. The police discovered that the water in the well was of "extraordinary odour" and sent a sample for analysis. Sulphuretted hydrogen gas in high concentration was found in the water.

Dhatura (Accidental poisoning).—Kalu Shah, his brother and daughter all lived together. Kalu, an old man with weak eye-sight, did the cooking. His brother had brought some dhatura with a view to kill rats. Kalu mistook this for chillies and used it in cooking. All

three became ill and senseless after partaking of the food. Kalu and his daughter vomited and recovered but his brother died. Dhatura seeds were detected in the vomited matter and stomach contents.

Cocaine.—A Muhammadan male, aged 25 years, was suspected of selling cocaine. When challenged by a police officer, he, in order to avoid further detection and to destroy all evidence against him, swallowed the cocaine packets in his possession. Within a very short time he lost consciousness and died.

Cocaine was detected in the stomach and its contents as well as in the liver, spleen and kidney.

Opium and Arsenic Suicide.—A young Sikh under-trial prisoner, aged 23 years, committed suicide while in police custody.

The chief symptoms before death were unconsciousness, deep breathing, frothing at the mouth and contracted pupils together with diarrhoea and vomiting.

Post-mortem appearances were those of death from asphyxia. There was also evidence of severe gastro-intestinal irritation.

Opium and arsenic were found in the viscera. It appears that he took both the poisons to make self-destruction a certainty.

Potassium cyanide.—A Muhammadan male, aged 35 years, was received in hospital in a dying condition—unconscious with cold clammy skin. Death occurred within a very short time. Post-mortem appearances consisted of general venous congestion, corrosion of the mucous membrane of the mouth, and odour of bitter almonds in the stomach. Potassium cyanide was detected in the stomach and intestine.

Opium (homicidal).—A few days' old baby disappeared. It was discovered later buried in the house by the police who suspected foul play. The body was too highly decomposed to permit of complete post-mortem examination. Viscera were sent for analysis. Opium was detected.

Opium (suicidal).—Young Hindu male, aged 22, took 2 tolas of opium with a view to commit suicide. Post-mortem appearances were typical, i.e., contracted pupils, general venous congestion and other evidences of asphyxia. A piece of opium weighing approximately 1 drachm was recovered from the stomach contents. Opium was also detected in other viscera.

Potassium Bichromate [accidental (surkh khai) poisoning].—A few persons purchased some poppy seeds from a shopkeeper and prepared "sardai" (cold drink). Shortly after their taking it, they began vomiting. Poppy seeds left unused with the complainants and a sample of poppy seeds obtained from the accused shopkeeper were received for examination. Potassium bichromate (surkh khai) was detected in the exhibits. It had got mixed up with the poppy seeds through the negligence of the shopkeeper.

The appointment of Chemical Examiner was held by Captain D. R. Thomas, I.M.S., up to 10th October, 1927, when he proceeded on leave. Major H. S. Anand, I.M.S., officiated during the remainder of the year.

ANNUAL REPORT OF THE ROSS INSTITUTE AND HOSPITAL FOR TROPICAL DISEASES FOR 1927. PUTNEY HEATH, LONDON, S.W.15.

THE annual report of the Ross Institute for 1927 is a record of continued progress in this important research centre. The following is a digest of the more outstanding items of interest:—

ROYAL VISITS.

The Institute was honoured by a visit of Queen Amelie of Portugal on July 13, 1927. The Queen was received by Her Grace the Duchess of Portland and members of the Ladies' Committee, and took great interest in all that was shown her at the Institute.

On November 28, 1927, H. M. the Queen of Spain paid a surprise visit to the Institute. Her Majesty was received by Sir William Simpson and Sir Aldo Castellani and showed particular interest in the question of malaria.

SPAIN.

Visit to Madrid by Sir Aldo Castellani.—At the invitation of the Spanish Government and in accordance with the express wish of Her Majesty the Queen of Spain when she visited the Institute, Sir Aldo Castellani went to Madrid on December 23 and gave several lectures on malaria. The first lecture delivered before the Royal Academy of Medicine was graced by the presence of Her Majesty.

Following this visit, His Majesty the King of Spain conferred upon Sir Aldo Castellani the Grand Cross of the Order of Civil Merit for his investigations in tropical diseases.

SEVENTH CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

This was held in Calcutta on December 5, 1927. An invitation to attend this Congress was extended to Sir Ronald Ross by the Government of India. Unfortunately, owing to illness, Sir Ronald Ross was unable to attend. Sir Ronald Ross and the Ross Institute were represented at the Congress by Sir Malcolm Watson, M.D. The Organising Secretary, Major H. Lockwood Stevens, met Sir Malcolm Watson in Calcutta, and also attended at the discussions in the Malaria Section.

At the termination of the Congress, Sir Malcolm Watson, as the guest of the Government of India, made an extensive tour of the northern part of the country, and on behalf of the Ross Institute and at the invitation of the Governments of the Punjab, the United Provinces and Burma, conferred with the Directors of Public Health of these Governments. He was also invited to the Central Provinces, but the Director of Public Health cancelled the engagement, and the tour was therefore not extended to Nagpur.

SIR RONALD ROSS REPORT.

There was a very large demand from India and the Colonies for the report on malaria control in Malay and Assam by Sir Ronald Ross, following his tour of inspection in 1926-27. The demand came to several thousand copies. This report was circulated freely by the Indian Tea Association, the Ceylon Association and the Rubber Growers' Association, and some hundreds of copies were distributed by the Ross Institute.

As there was a heavy demand from India, the Institute gave permission to the Educational Department of the Government of India to reprint the report and use same as required. Certain Indian Princes asked for the report and the Institute sent several hundred copies to meet this demand. A few of these reports are still available for distribution, and the report is very instructive to laymen.

Anti-malaria Propaganda Work.—In order that the Committee might have a good general idea of the manner in which malaria was being dealt with in different parts of the Empire, the Organising Secretary, Major H. Lockwood Stevens, went out to India in November and met Sir Malcolm Watson in Calcutta. Major Stevens afterwards made a tour of India, the Federated Malay States and Ceylon, and also visited Colonel Bisset and Major Jolly in Burma. His tour will be the subject of a special report.

One of the Vice-Presidents, Sir Dorabji Tata, realising the value to India of this investigation, most kindly placed £350 at the disposal of the Committee, to be used for the purpose of this tour. The Committee is very grateful indeed for the gift by Sir Dorabji Tata.

It is with much pleasure that the Executive Committee inform members of the Institute and subscribers that Sir Malcolm Watson, who has now retired after many years' active malaria control work in the Malay States, has arrived in England and has joined the Institute as Principal of the Malaria Prophylaxis and Control Department.

The British Mosquito Control Institute.—In the last report it was suggested that advantage should be taken of the practical knowledge which could be given

27. Dr. Deviprosanna Basu.
28. Dr. Panchanon Chatterji.
29. Dr. N. Chandra.
30. Dr. S. N. Bagchi.
31. Dr. B. C. Ghose.

ROYAL INSTITUTE OF PUBLIC HEALTH.

A FULL course of instruction necessary for obtaining the Diploma of Public Health can be obtained at the Royal Institute of Public Health, 37, Russell Square, London, W.C.1.

The course is divided into five subjects, namely, Chemistry, Bacteriology and Parasitology, Hygiene and Sanitation, Public Health Administration, and Fever Hospital Administration and Clinical Practice. In addition there are special lectures on important subjects connected with public health.

Further details about this course may be obtained from the Secretary at the above-mentioned address.

"CURE FOR LEPROSY."

Esthonian Doctor's Preparation.

THE following *Reuter's* message appeared in the public press at the end of October last:—

Riga, Oct. 18.

"Four lepers have been released from the Esthonian leper asylum on the island of Oesel as completely cured. They were treated with a gold preparation called 'Solganal' prepared by Dr. Feldt of Riga, who has been experimenting with it since 1914, and who is now working in the Koch Institute for infectious diseases at Berlin."

Schering-Kahlbaum (India), Ltd., are the agents in Calcutta for this preparation.

MAMMARY COMPLICATIONS AND THEIR TREATMENT.

THE management of the breasts during pregnancy and the puerperium is receiving more and more attention these days, owing to the emphasis pediatricians now place on the importance of breast-feeding as one of the best safeguards against disease in infancy.

Alfred C. Beck, M.D. ("Care of the Breast during Pregnancy and the Puerperium," *American Journal of Nursing*, August, 1928), points out that the underlying factors in the failure of lactation usually are: (1) tender and fissured nipples; (2) painful engorgement of the breasts; (3) the anxiety of the mother concerning her inability to nurse her child; and (4) the supplementary feeding, and concludes that a proper routine must aim at avoiding or relieving these conditions. The management of the breasts must also include every possible means of preventing infection, since mastitis is not only a serious maternal complication, but its treatment requires the discontinuance of nursing and thereby it becomes an additional factor in the loss of breast secretion.

The treatment of *fissures*, which are the usual forerunners of *mastitis*, is similar to the treatment of small wounds in other parts of the body. Under a routine of cleanliness, rest and the antiphlogistine treatment, this troublesome complication rapidly disappears. Absolute rest can be obtained only by discontinuing the nursing on the affected breast. Schreiner ("Shall the child nurse in the presence of mastitis?"—*Zentralblatt für Gynäkologie*, Vol. 48, 1924), after observing cases of mastitis among 5,252 patients in the Cassel Hospital, concludes that at the first clinical appearance of mastitis,

nursing should be interrupted, and the breast placed absolutely at rest and treated with antiphlogistics. This gives satisfactory results in 90 per cent. of the cases, and the temporary removal of the child until the disappearance of inflammation; is followed by permanent loss of secretion in only a very small percentage of cases.

Painful engorgement of the breasts calls for a breast sling, so adjusted as to give support without compression. During the intervals between nursings, applications of hot antiphlogistine will serve to deplete the engorged areas and induce relaxation of the inflamed tissue.

To sum up, the rules laid down for the treatment of inflammatory processes in general have the same application to inflammatory disease of the breasts.

A COINCIDENCE IN PHARMACEUTICAL HISTORY.

AN interesting event in medical progress is the recent synthetic production of Ephedrine by E. Merck, Darmstadt. The preparation is being marketed under the trade name of *Ephetonin*.

This recalls the original isolation of the alkaloid (from *Ephedra vulgaris*, var. *helvetica*) by Merck in 1888, after which this ancient Chinese medicament passed through a period of quiescence until 1925, when fresh examination of its pharmacological properties by Chen awakened world-wide interest and investigation.

A heavy demand was naturally soon created for this drug, which suddenly emerged from obscurity into a position of prominence in modern medical practice, where it is proving of specific value in the treatment of bronchial asthma, hay-fever, hypotonia, etc.

Difficulty in obtaining adequate supplies of the correct species of Ephedra led to experiments in the laboratories at Darmstadt with a view to its synthetic preparation, and the result is *Ephetonin*, which other than being optically inactive is identical pharmacologically with Ephedrine.

Ephetonin possesses precisely the therapeutic properties of its natural analogue and is distinguished by its constant effect, low toxicity and ease of administration—it may be given orally, and for that purpose is conveniently issued in the compressed form, but it also is supplied in ampoules.

Its superiority over adrenalin should lead to its supersession of that drug in asthmatic and allied affections. *Ephetonin* should prove a valuable addition to our *Materia Medica*.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

HOMOGENITISURIA (ALKAPTONURIA) WITH GLYCOSURIA.

WITH NOTES ON A DETAILED CLINICAL AND CHEMICAL INVESTIGATION OF A CASE.

By J. P. BOSE, M.B., F.C.S. (Lond.),
Diabetes Research Worker, School of Tropical Medicine,
Calcutta,

and

SUDHAMOY GHOSH, D.Sc., F.R.S.E.,
Professor of Chemistry, School of Tropical Medicine,
Calcutta.

Introduction.—According to Sir Archibald Garrod, "Alkaptonuria is an extremely rare anomaly and less than fifty cases in all have so far been recorded. In the great majority, at any rate, it is a congenital, lifelong, harmless peculiarity which is apt to occur in several brothers and sisters of a family. It is seldom directly transmitted from parent to child, but in a large proportion of cases, the subjects of it have been the offspring of consanguineous marriages."

It occurs in individuals, otherwise normal, whose urine, though of perfectly normal colour when freshly passed, turns black when exposed to air, especially if rendered alkaline.

Cuthbert (1923) reported the case of three alkaptonuric children who were the issue of marriages between first cousins. Debenedetti (1920) recorded a family with a higher proportion of alkaptonuric members, the issue of parents who were first cousins. In the present case, the patient's parents were relations, but the exact relationship between them could not be ascertained.

Cuthbert also notes that among the alkaptonuric members of a family, there is usually a much larger proportion of males than females. Lewis also supports this observation.

Garrod (1908) in an admirable monograph on the "Inborn errors of metabolism," has discussed the subject in some detail and has described these cases along with other anomalies (such as cystinuria, pentosuria, albinism) as "chemical malformations" of hereditary origin.

Though rare, medical men ought to know more about it and the modern methods for its recognition, so as not to mistake it for illness of a graver nature. It has been observed in infants from the earliest days of life. Alkaptonuria, as has already been stated, causes practically no discomfort to the person suffering from it, nor has it, so far as is known, any ill effect on the person's health. Some patients have complained of vague articular pains (e.g., in the case under report) and in others, a peculiar staining of the cartilages has been observed (Ochronosis, described by Virchow in 1886).

The first suspicion as to there being something wrong with the individual usually takes

place when the alkaptonuric goes for life insurance. Homogentisic acid, which is present in the alkaptonuric urine, being a strong reducing agent, is mistaken for sugar and the person is refused. Some patients have brought to the notice of the doctors that the underwear gets deeply stained owing to the urine coming in contact with it. As a matter of fact, this latter peculiarity helps in its recognition at the very beginning of life and Garrod has recorded two cases in which the staining was noticed on the second day of life.

Alkaptonuria should prove to be of special interest to the chemical physiologist and pathologist. The study of this disease by eminent research workers of the type of Wilkow, Baumann, Marshall, Kirk, Boedeker and Garrod has materially helped to advance our knowledge of the intricate problems of protein metabolism.

On a review of the literature on the subject, it would appear that this disease was recognized nearly 350 years ago. Scribonius in 1584 mentioned the case of a school boy "who although he enjoyed good health, continuously excreted black urine." Schenck in 1609 cited the case of a monk "who exhibited a similar peculiarity and stated that he had done so all his life." In 1649, Zacutus Insitanus published a very interesting case of this nature. "The patient was a boy who passed black urine and who, at the age of 14 years, was submitted to a drastic course of treatment which had for its aim the subduing of the fiery heat of his viscera, which was supposed to bring about the condition in question, by charring and blackening the bile. Among measures prescribed were bleeding, purgation, baths, a cold and watery diet and drugs galore.... None of the predicted evils ensued, he married, begat a large family and lived a long and healthy life, always passing urine black as ink."

It must be mentioned here that these early workers did not draw any distinction between urine which was black when passed and that which darkened on exposure to air. To all intents and purposes, however, the cases referred to above point to the diagnosis of alkaptonuria. Marcet in 1823 accurately described the case of an infant whose urine darkened in colour on standing, this reaction being accelerated by the addition of alkali, and also noted the properties of the urine in staining linen. Marcet, however, failed to recognize the reducing properties of such urine. In 1858, Boedeker detected in the urine of a patient with glycosuria "a second reducing substance, not a sugar, to which, on account of its behaviour towards alkalies, he assigned the name of *alkapton*, a bilingual word derived from alkali and *καπτείν* (to absorb greedily)."

Marshall in 1887 isolated a substance from the urine of his patient and he designated it as glycosuric acid (because it had reducing properties like

glucose); it had the following formula:—

Kirk (1888, 1889) isolated an acid from alkaptonuric urine which he named uroleucic acid, having a melting point of 133.3°C ., had to which he gave the following formula:—

It will thus be seen that these two workers, Marshall and Kirk, went very near to the isolation and composition of the abnormal substance in the urine which, however, was finally isolated five years later by Wilkow and Baumann (1891) and on investigation was found to have the empirical formula $\text{C}_6\text{H}_8\text{O}_4$, having a melting point of 146° to 147°C . Wilkow and Baumann's work has subsequently been confirmed by the work of Huppert, Frankel, Osborne, Otto Neubauer, Garrod and others.

Chemistry.—As the result of the investigations of the workers mentioned above, it was definitely proved that the constitution of homogentisic acid is 2,—5-dioxy-phenyl acetic acid (hydroquinone acetic acid) and its structural formula is as follows:—

Its melting point, as has just been said, is between 146° and 147°C .

Homogentisic acid is believed to be derived from phenyl-alanine and tyrosine in the body, and it has been experimentally proved that, in alkaptonuric individuals, the homogentisic acid is markedly increased when phenyl-alanine or tyrosine is administered by mouth (Falta & Langstein, 1902 and 1903). Protein foods have also been found to increase the output of homogentisic acid in these individuals. The usual average output of homogentisic acid in the urine of alkaptonuric individuals is stated to be from 3 to 6 grammes daily.

From a study of experimental observations, it appears that alkaptonuria results from a disturbance of the catabolism of the amino-acids, particularly tyrosin and phenyl-alanine, in such a way that the final cleavage of the benzene ring beyond the stage represented by homogentisic acid is no longer possible in these individuals. Garrod also supports this theory.

Treatment.—On reviewing the literature, very little information is obtained regarding the treatment of this anomalous condition.

Various remedies have been tried and suggested by different authorities; Wilkow and Baumann, for instance, suggested that this condition

might have its seat in the intestines of alkaptonurics, being brought about by the influence of "a rare specific micro-organism." This infective theory has now been completely abandoned, because intensive intestinal disinfection has no influence upon the excretion of homogentisic acid by alkaptonurics nor can any "specific" organism be grown from their faeces.

Barr and Freund (1926) injected serum and milk in an infant 10 months old with alkaptonuria. The excretion of homogentisic acid dropped after the injection.

Volzt (1924) suggested that restriction of albumen intake, specially of casein, should be tried.

Potassium iodide has also been recommended.

In the case under report, investigation as regards treatment by various agents (both dietetic and medicinal) is still being carried on, but the results obtained so far are not of sufficient importance to justify publication.

Case.

R. M., Madrassi Hindu male, age 55 years, was admitted under one of us (J. P. B.) in the Carmichael Hospital for Tropical Diseases for "long standing diabetes" on the 14th July, 1928. The patient was a healthy well-built man of short stature.

Family history.—Father died at the age of 55. His mother, (the second wife of his father) was still living. The patient stated that his parents were relations but the exact relationship he was not aware of. He had 5 brothers and 2 among them were said to be diabetic. Sisters were four in number.

Past History.—The patient said that he had always been a sober man and had never touched alcohol in his life, nor did he eat fish, meat or eggs, being a high caste Hindu. He smoked tobacco moderately. His chief diet had always been rice, dal, vegetables, milk, butter, etc. The patient stated that his clothes used to be stained chocolate brown from birth and that his mother who noticed it used to remark that he would not live long.

Present complaints.—Vague fleeting articular pains in nearly all the joints of his body; duration about 12 years. Frequency of micturition and thirst; duration, the same. The patient had never had his urine examined before. Appetite good. Bowels regular. General appearance, good.

Physical examination.—Mouth, pyorrhœa; tongue, coated and moist. No enlarged cervical or submaxillary glands. Movements of chest, normal. In both lungs, a few rhonchi present, otherwise breath sounds normal. Anæmia, nil. Jaundice, nil.

Circulatory system.—*Blood-pressure.*—Systolic: 115, diastolic: 80. Apex beat, normal; no cardiac abnormalities found. Response to exercise, good. Pulse, normal; no evidence of arterio-sclerosis.

Abdomen.—Liver, not enlarged. Spleen, not enlarged. Stomach, normal. Colon, normal.

Nothing abnormal in the *genito-urinary* system. Nothing abnormal in the nervous system or in the special senses.

Blood reaction for syphilis: Wassermann test, negative.

Blood for parasites: no parasites.

Date.	Diet.	Carbo-hydrate.	F CD-VALUE IN DIET.			Body-Wt. (lbs.)	REMARKS.
			Protein.	Fat.	Calories.

LABORATORY TESTS.

Blood.

Blood reaction for kala-azar: antimony test in serum,—negative, aldehyde test in serum,—negative.

Blood reaction for T.A.B., Widal test, T., 1/10. A.B., 1/20.

Blood reaction for dysentery: agglutination against dysentery bacilli, negative.

The serum was tested for homogentisic acid but the result was negative.

Blood chemistry.

Blood sugar, 0.160 per cent. or 160 mgs. per 100 c.c.

Blood, non-pratun nitrogen 0.025 per cent. or 25 mgs. per 100 c.c.

Blood urea, 0.015 per cent. or 15 mgs. per 100 c.c.

Blood uric acid, 0.0019 per cent. or 1.9 mgs. per 100 c.c.

Blood count.

Hæmoglobin, 95 per cent.
Red Blood Corpuscles, 5,590,000 per c.mm.
White blood cells, 9,800 per c.mm.
Polymorphonuclears, 64 per cent.
Small mononuclears, 31 per cent.
Large mononuclears, 4 per cent.
Eosinophiles, 1 per cent.
Parasites, nil.

Stools.

No non-lactose fermenters. Oxyuris and ascaris ova, and *E. histolytica*, all present.

X-Ray examination could elicit nothing abnormal in the joints.

Body-weight on admission.—104½ lbs.

FUNCTIONAL TESTS.

Lævulose-tolerance test.

Blood-sugar before giving lævulose, 0.160 per cent.

Blood-sugar 1 hour after 25 gms. of lævulose, 0.130 per cent.

Blood-sugar 1½ hours after 25 gms. of lævulose, 0.146 per cent.

Result.—Normal.

Van den Bergh's test.—Normal.

Glucose tolerance test:—

Blood-sugar before giving glucose .. 0.164 per cent.

" ½ hour after 50 grammes of glucose .. 0.224 "

Blood-sugar 1 hour after 50 grammes of glucose .. 0.320 "

Blood-sugar 2 hours after 50 grammes of glucose .. 0.238 "

Remarks.—Sugar tolerance definitely defective.

Kidney function test.—Result of Maclean's urea-concentration test—normal.

Chemical examination of the urine:—

Colour.—Straw and clear when freshly passed, but on the surface being exposed to air, it gradually darkened in colour. This reaction was found to be accelerated by the addition of alkalis. This is represented in the photograph given below (Fig. 1).

Fig. 1.

Specimen marked I, is a sample of freshly passed urine. Note that the colour is perfectly uniform.

Specimen marked II, is a sample of urine from the same patient allowed to stand exposed for 6 hours. Note that the top layer of the urine about an inch deep has turned jet black. The lower portion of the urine also is gradually turning darker.

Specimen marked III, is another sample of urine from the same patient exposed for 18 hours. Note that nearly the whole of the sample has turned inky black.

Reaction.—The freshly passed urine was found to be acid in reaction, but when exposed for a short time, it gradually turned alkaline along with the darkening in colour noted above.

Tests for albumen, diacetic acid, indican and urobilin were all negative.

Nothing abnormal was detected on microscopical examination.

Tests for sugar:—

(1) *Fehling's test*.—When the urine was added to Fehling's solution in the cold, the deep blue colour of the reagent became gradually lighter and finally assumed a greyish-black colour with a greenish tinge. When the Fehling's solution and the urine were boiled separately and then mixed, the above change took place immediately, with the formation of a definite precipitate.

It may be noted here that these characteristic changes are quite unlike those due to the presence of sugar alone in the urine.

(2) *Benedict's test*.—Benedict's solution treated with the urine gave results similar to the above.

(3) *Nylander's test*.—Nylander's solution in the cold turned dark brown when the urine was added. On boiling, a precipitate was observed.

(4) *Fermentation test*.—The urine incubated in Einhorn's tube for 18 hours with brewers' yeast, gave definite evolution of CO₂.

(5) *Osazone test*.—Some crystals of phenyl-glucosazone were observed by treating the urine with phenyl hydrazine hydrochloride. The presence of glucose was further established by separating the homogentisic acid and preparing the glucosazone in the following way:—

The urine was treated with a solution of basic lead acetate until there was no more precipitate. The filtrate was freed from lead by treating with H₂S. It was filtered again and H₂S was removed by boiling. The clear solution was then treated with phenyl hydrazine and acetic acid and a fair amount of definite yellow crystals characteristic of phenyl-glucosazone was obtained. The separation of these crystals in a purer form and the determination of their melting point are described later on.

The tests mentioned above gave us a definite clue as to the presence of homogentisic acid in the urine, besides glucose. After applying some of the recognised tests for homogentisic acid in the urine, the following results were obtained:—

(1) When treated with ammonia and shaken in contact with air, there was a gradual deepening of colour from brownish red to dark brown.

(2) With a dilute solution of ferric chloride, a fleeting blue colour was observed. This reaction is very rapid and must be observed very carefully.

(3) With silver nitrate solution (about 10 per cent.) a gradual reduction to metallic silver took place even in the cold.

(4) With an ammoniacal solution of silver nitrate, the above reaction was much more rapid.

(5) A few drops of an ethereal extract of urine, when dropped upon a little powdered lime (CaO), developed a blue colour which gradually disappeared again.

These results left us in no doubt as to the presence of homogentisic acid in the urine and we proceeded to isolate it, and estimate it quantitatively in the following way.

Isolation and purification of homogentisic acid:—

The urine was acidified with sulphuric acid (1 in 12), using 75 c.c. of the dilute acid for every litre of urine, and evaporated on the water-bath to about 1/10th of

its bulk. Three litres of urine were treated in this way. The concentrated residue was taken in a separating funnel and shaken repeatedly with ether until the homogentisic acid was exhausted. Most of the ether was recovered and the concentrated ethereal solution, treated with freshly ignited anhydrous sodium sulphate to remove all moisture and the impurities held in solution, was then filtered and the ether evaporated. The residue was taken up in water and filtered from fatty and other impurities. The aqueous solution was warmed on the water-bath and a concentrated, (about 50 per cent.) hot, aqueous solution of neutral lead acetate added and quickly filtered from the slight amount of precipitates that had formed. On cooling, a large quantity of crystalline precipitate appeared. When observed under the microscope, the crystals were seen to possess the characteristic needle shape of lead homogentisate $(C_6H_5O_4)_2 Pb \cdot 3H_2O$ as described by Garrod and others (see Fig. 3). The crystals were left overnight to settle in a cool place and filtered the next day. They were washed with a little cold water, dried on a porous plate and then left in a vacuum desiccator over concentrated sulphuric acid. The first precipitate with lead acetate obtained above was also treated in the same way. It was found to be somewhat impure lead-homogentisate and was not mixed with the second purer lot used for the preparation of pure homogentisic acid. Both the dry lead precipitates were weighed and used for the estimation of homogentisic acid (see later). For the preparation of homogentisic acid, the second purer lot of the dry powdered lead salt was suspended in ether in a conical flask, cooled over ice-water, and a current of sulphuretted hydrogen passed for about half-an-hour. The ethereal solution was filtered into a weighed glass dish and the residual lead precipitate again suspended in ether and treated with H_2S . The process was repeated until all the lead homogentisate was decomposed. The ether was removed and the residue dried in a vacuum over sulphuric acid. The homogentisic acid thus obtained was crystalline and of a light yellow tinge. It was purified by dissolving it in a very small amount of hot absolute alcohol and adding pure chloroform to it. On scratching with a glass rod, colourless crystals separated and were rapidly dried on a porous plate and washed with a little chloroform. The crystals melted at $146^\circ C$. (theoretical $146^\circ-147^\circ$) and appeared under the microscope as colourless transparent leaflets (see Fig. 2). They were easily soluble in water, alcohol and ether but almost insoluble in chloroform and benzene.

Fig. 2.

Reactions observed with the pure homogentisic acid isolated as above:—

(1) With ammonia, caustic soda or sodium carbonate, the aqueous solution turned brown and the colour deepened gradually.

(2) An aqueous solution reduced silver nitrate even in the cold. An ammoniacal solution of silver nitrate was rapidly reduced even in the cold.

(3) Ferric chloride added drop by drop to an aqueous solution of homogentisic acid produced a fleeting blue colour.

(4) An aqueous solution gave a lemon yellow colour and finally a precipitate with Millon's reagent. The precipitate turned brick-red on warming.

(5) An ethereal solution of the acid when dropped upon a thin layer of lime (CaO) developed a beautiful deep blue colour which soon disappeared again.

Derivatives of homogentisic acid:—

(1) *Lactone*.—On heating the pure acid in a dry test-tube, prismatic crystals of lactone sublimed on the upper part of the tube.

(2) *Lead homogentisate*.— $(C_6H_5O_4)_2 Pb \cdot 3H_2O$. A hot aqueous solution of the pure acid was treated with a concentrated (50 per cent.) clear aqueous solution of neutral lead acetate and on cooling, a copious colourless crystalline precipitate came out. Under the microscope, the crystals were found to consist of long colourless needles (see Fig. 3). The crystals were washed with a little water, dried on a porous plate and finally in a vacuum over H_2SO_4 . They melted at $210^\circ C$.

Fig. 3.

(3) *Di-benzoyl-homogentisamide*, $C_6H_5(O.C_6H_5CO)_2 CH_2.CO.NH_2$. About 0.5 gramme of homogentisic acid was dissolved in a little water in a conical flask, some dilute $NaOH$ added until it was alkaline and then about 2 c.c. of conc. ammonia. About 5 c.c. of benzoyl chloride was then poured in and the flask shaken constantly while the liquid was kept alkaline with constant addition of small amounts of 40 per cent. $NaOH$. When the odour of benzoyl chloride disappeared, the flask was kept aside to settle. The red-coloured crystals which separated out of the alkaline solution were filtered and washed with warm water. They were then crystallised from boiling absolute alcohol with the addition of some animal charcoal. The colourless crystals obtained were again recrystallised from absolute alcohol and finally dried in *vacuo* over H_2SO_4 . Colourless needles appeared of which the melting point was $202^\circ C$.

Confirmation of the presence of glucose:—

The concentrated aqueous solution (from 3 litres of urine), after extraction of homogentisic acid with ether, was neutralised with caustic soda, filtered and made up to a known volume (see estimation of glucose). A portion of the aqueous liquid was treated with basic lead acetate until there was no more precipitate. It was filtered and the filtrate freed from lead by H_2S . The filtrate from PbS was freed from H_2S and the rotation of the solution examined in a delicate polarimeter. The solution was found to be dextro-rotatory and pointed to the presence of "d"-glucose. It was further confirmed by the preparation of osazone from the same solution with the help of phenyl hydrazine and acetic acid. The osazone was recrystallised twice from alcohol and dried in a vacuum desiccator over

H₂SO₄. It melted at 110°C. (melting point of phenyl-glucosazone on somewhat rapid heating, 110°C.). The crystals seen under the microscope had the characteristic needle-like shape of phenyl-glucosazone.

Approximate estimation of glucose:—

An aliquot part of the neutral aqueous solution used for the preparation of osazone, was treated as before with basic lead acetate and filtered quantitatively. The filtrate was freed from lead and subsequently from H₂S and made up to a known volume. From the amount of reduction of Fehling's solution observed, the concentration of sugar, calculated as glucose, was found to correspond to 0.30 per cent. of glucose in the original urine. The amount obtained by observing the rotation was somewhat lower, owing perhaps to partial racemisation by heat.

Estimation of homogentisic acid.—We first tried the simple method suggested by Garrod (1898) for the estimation of homogentisic acid directly from the fresh urine, but the method was not found satisfactory, owing perhaps to the smaller excretion of homogentisic acid in the present case than in those observed by Garrod. The method of Wilkow and Baumann was therefore followed by us with the slight modification as described before under the isolation of the acid. The total dry lead homogentisate amounted to 6.42 grams. Since 1 gram of lead homogentisate (C₆H₇O₄)₂. Pb. 3H₂O is equivalent to 0.564 gram of homogentisic acid C₆H₈O₄, the lead homogentisate isolated from 3,000 c.c. of urine is equivalent to 6.42 by 0.564 or 3.62 grams of homogentisic acid. Hence the concentration of homogentisic acid present in the original urine,

$$\frac{3.62 \times 100}{3000} = 0.12 \text{ per cent.}$$

The daily excretion of homogentisic acid was not constant, as was noticed by the physical appearance of the urine, and the above figures for glucose and homogentisic acid are only for a particular period.

The name *alkaptomuria* should in our opinion be changed to *homogentisuria*. The old name which had its origin in the belief that "alkapton bodies" were excreted in the urine, cannot be supported any longer after it has been definitely proved that it is homogentisic acid that is responsible for these peculiar reactions in the urine. We, therefore, suggest the name "homogentisuria," like similar scientific names such as glycosuria, pentosuria, albuminuria, etc.

In conclusion, we desire to express our best thanks to Mr. U. N. De, B.Sc., Research Chemist, Diabetes Inquiry, for helping us in our experiments. We also desire to thank Sister North and Staff Nurse Vardon for helping us in the collection of materials.

THE SPREAD OF DYSENTERY IN A KHASI VILLAGE AND ITS TREATMENT WITH BACTERIOPHAGE.*

By B. K. PAL CHOUDHURY, B.Sc., M.B.,

and

J. MORISON,

LIEUTENANT-COLONEL, I.M.S.,

Pasteur Institute, Shillong.

ON the 7th May two men came from the village of Sohjarang saying that the villagers of a neighbouring village, Nongsier, had nearly all died of dysentery and that now Sohjarang was affected, many were ill and three children had died.

Sohjarang is a Khasi village in the jungle 12 miles west of the Shillong-Gauhati Road. It consists of 29 houses and 161 inhabitants. The main village has 24 houses clustered on the slopes of a hill and a smaller part consists of 5 houses on a neighbouring hill. This portion is referred to as U. Pher's village.

The people of Nongsier are related to families in Sohjarang and, though ten miles separate the two villages, there is frequent intercourse and there is a reasonable probability that, as the villagers affirm, the disease came from Nongsier.

On Dr. Choudhury's arrival there on the 9th May he found 68 persons actually ill with dysentery; five others had already died. The epidemic seems to have begun on the 25th April and within three days there were eleven cases in seven houses distributed through the village. The epidemic seems divisible into three waves. The first lasting from the 25th April till the 30th April, the second from the 1st May to the 7th May and the third from the 8th May till the occurrence of the last case on the 17th May. In each wave the cases were distributed throughout the village. The disease did not begin at one end of the village and spread to the other nor is there evidence that there was any concentration of cases in adjoining houses. Only two houses, the one occupied by a mission teacher who lives alone and the other by a woman also living by herself, escaped attack in the main village. Three out of five houses escaped in U. Pher's hamlet.

The scattered distribution of the cases in each of the three outbursts and the absence of any concentration of the cases is against the spread

*Read at the Annual Meeting of the Assam Branch of the British Medical Association.

of the infection by contacts or by flies. The successive waves and the scattered distribution suggest a distribution by water.

The water supply of the main village comes from a spring buried in jungle to the east of the village. So dense is the jungle that the spring is inaccessible to human beings. The jungle is not used for purpose, of nature. The water is led out of the jungle through a bamboo pipe from the end of which water is drawn.

The houses of the village are on bamboo platforms one end of which almost rests on the hill and the other is supported by posts several feet high. On the half of the platform next the hill is the grass hut. The other half is uncovered and is used for sitting out, and for drying food and clothes. In this part of the platform is a hole which is the latrine. The night-soil, dropping on the ground below, is disposed of by the pigs, of which each hut has one or more. The pigs have only the small stream of water from a bamboo pipe to drink from but they also can find their way to the spring in the jungle.

Dr. Choudhury had the jungle cut and exposed a pool of water 30 feet long, 2 feet wide and 16 inches deep. The bamboo pipe led off from the lower end of the pool. He had a fence put round the pool on the 11th May and the last case occurred six days later. There were no new cases during the remaining six days of his stay.

It would seem that this epidemic was water-borne and that the pool was successively infected by pigs that had fed on dysenteric stools.

The object of Dr. Choudhury's visit was to test the use of bacteriophage under village conditions. Six villagers were each placed in charge of five houses and the bacteriophage diluted with water was sent round in bottles. A dose of 2 c.cm. in about 4 oz. of water was given to every sick person on the first day three times and subsequently twice daily.

No milk was available in the village and the only food that could be given to the sick was a paste of boiled rice and water. They were given as much water as they cared to drink.

Dr. Choudhury brought clinical reports of all the cases. They are divisible into severe cases who were passing stools 'constantly'; moderately severe cases with 6 to 15 stools a day with or without fever; and mild cases with less than 6 stools a day. All were actually passing dysenteric stools.

The results were:—

	Severe.	Moderately severe.	Mild.
Number	.. 18	19	43
Deaths	.. 3	0	0

The deaths were two infants and one adult. One infant when first seen had extensive aphthous ulceration of the whole mouth resembling the action of a corrosive acid. The other was so feeble that it could not be fed. The

adult had been eight days ill and passed blood and mucus every few minutes. Six days later the stools became faecal and were reduced to three but the patient was so feeble that she could not swallow food. Only a severe case, not included in the statistics, refused treatment and was still ill when Dr. Choudhury left after 14 days' stay.

Of those treated all but seven had by that time resumed their work. One, a moderately severe case, walked to Shillong and back (a total distance of 50 miles) within a week of his illness with no ill effect.

The seven remaining cases were convalescent and a few days later were reported by the headman to have recovered.

Forty-three samples of stools were sent day by day to the Pasteur Institute, Shillong. The journey took 24 hours but notwithstanding this delay *B. dysenteriae* (Shiga) was isolated three times and *B. dysenteriae* (Flexner) four times. The outbreak was one of bacillary dysentery. It seems to have been caused by pigs and the treatment of the cases with live atylage under singularly difficult conditions satisfactory results.

to see if
used in

BERBERINE IN THE TREATMENT OF ORIENTAL SORE.

By ASSISTANT SURGEON B. M. DAS GUPTA,
Assistant Professor of Protozoology,
and

B. B. DIKSHIT, M.B., B.S., D.P.H.,

Department of Pharmacology,

School of Tropical Medicine and Hygiene, Calcutta.

BERBERINE is an alkaloid chiefly obtained from the bark of *Berberis vulgaris* and other species of barberry, although it also occurs in certain proportions in hydrastis, calumba, etc. The alkaloid and its salts are bright yellow in colour and possess an intensely bitter taste. This latter property has been made use of in therapeutics and the drug has been used as a bitter tonic. It has also been used in diarrhoea and in the diagnosis of latent malaria (sabutini, 1928), its use in therapeutics, however, being very limited. The alkaloid berberine has the formula $C_{20}H_{17}NO_4$. Its salts—the hydrochloride and the sulphate—are sparingly soluble in water. The latter is the more soluble—the solubility being approximately 1 in 100.

Although the drug has been included in the pharmacopœia for a number of years, its remarkable effect in the treatment of local leishmaniasis was observed only recently. Varma (1927) was the first to use berberine sulphate successfully in the treatment of oriental sore. He refers to the work of Jolly (1911) who tried "rasout", a paste made from berberis with not very satisfactory results. Varma tried the paste but found it useless and initiated the use of berberine sulphate given hypodermically, infiltrating the sore. With this method he obtained remarkable results, the sore completely healing up after 2 or 3 injections given at weekly intervals.

Karamchandani (1927) studied a few different methods of treating the sore and reported that the injection of berberine sulphate was the most successful of all. The drug, as far as we know, did not receive any clinical trials after this, and no laboratory study of its action on *Leishmania tropica* has been made up to the present. We, therefore, under the guidance and at the suggestion of Lieut.-Cols. H. W. Acton and R. N. Chopra undertook to study the effects of the drug clinically as well as in the laboratory. The toxicity of berberine sulphate was studied on cultures of *Leishmania tropica* and *L.*

donovani. To seven tubes containing 4.9 c.c. of a modified N.N.N. medium, 0.1 c.c. of sterile distilled water containing different amounts of berberine sulphate was added, so as to give total dilutions of the drug varying from 1 in 1,000 to 1 in 100 million. The seventh tube was kept as a control. The tubes were incubated for 24 hours to test their sterility and then inoculated with a four-day-old culture of *L. tropica* and of *L. donovani*. After incubating for four days at 22°C., the tubes were examined for the growth of the organisms. The following table explains the results obtained.

TABLE I.

Shows the growth of flagellates obtained after inoculating tubes of N.N.N. medium containing varying quantities of berberine sulphate with *L. tropica* and *L. donovani*.

	Concentration of berberine sulphate.						Control.
	1—1,000	1—10,000	1—100,000	1—1 mil.	1—10 mil.	1—100 mil.	
<i>L. tropica</i>	—	—	+	+	+	+	+
<i>L. donovani</i>	—	—	+	+	+	+	+

It will be seen from the table given above that a 1 in 10,000 concentration of the drug inhibits the growth of *L. tropica* as well as of *L. donovani*, while a strength of 1 in 100,000 does not inhibit the growth of these organisms. To determine

the toxicity more accurately the experiment was repeated as before, using concentrations varying between 1 in 10,000 and 1 in 100,000. The results are tabulated below.

TABLE II.

Shows the growth of flagellates obtained after inoculating tubes of N.N.N. medium containing concentrations of berberine sulphate varying from 1:10,000 to 1:90,000 with *L. tropica*.

	Concentration of berberine sulphate.									Control.
	1—10,000	1—20,000	1—30,000	1—40,000	1—50,000	1—60,000	1—70,000	1—80,000	1—90,000	
<i>L. tropica</i>	—	—	—	—	—	—	—	—	+	+

A dilution as high as 1 in 80,000, therefore, completely inhibits the growth of the organism.

A comparative study with protoplasmic poisons like quinine and emetine was then made to deter-

mine the toxicity of these powerful alkaloids on the growth of *L. tropica*. The following table gives an idea of the relative action of these drugs on the growth of *L. tropica*.

TABLE III.

Shows the growth of flagellates obtained after inoculating tubes of N.N.N. medium containing various proportions of quinine and emetine with *L. tropica*.

	Concentration of the alkaloid.						Control.
	1—1,000	1—10,000	1—100,000	1—1 mil.	1—10 mil.	1—100 mil.	
Emetine hydrochlor.	+	+	+	+	+	+	+
Quinine bi-hydrochlor.	—	+	+	+	+	+	+

Only quinine, in strength as high as 1 in 1,000, is able to inhibit the growth of the organism, whilst in 1:1,000 emetine they were still alive.

We next tried the effect of Stibosan, which is a popular remedy for oriental sore and visceral leishmaniasis, on the growth of *L. tropica*. The results are tabulated below.

microscope. Berberine sulphate in a strength of 1 in 200 kills the leishmania immediately. Weaker solutions were also tried, but as they do not kill the organisms immediately and formed a precipitate with the blood of the media, no inference could be drawn from the experiments.

TABLE IV.

Shows the growth of flagellates obtained after inoculating tubes of N.N.N. medium containing different amounts of Stibosan with L. tropica.

GROWTH +				No GROWTH -			
L. Tropica ..	Concentration of Stibosan.						
	1-1,000	1-10,000	1-100,000	1-1 mil.	1-10 mil.	1-100 mil.	Control.
	+	+	+	+	+	+	+

As will be seen from the table given above Stibosan even in concentrations as high as 1 in 1,000 does not check the growth of *L. tropica*. Still stronger concentrations were, therefore, prepared to try to determine the strength of Stibosan which can effectively check the growth of this parasite. In these experiments 0.5 c.c. of distilled water containing varying amounts of Stibosan was added to 9.5 c.c. of culture medium so as to give total dilutions ranging from 1 in 500 to 1 in 100. To reach the strength of 1 in 100, 0.5 c.c. of a 1 in 5 solution of Stibosan was used, and as higher strengths than 1 in 5 could not be prepared, it was found impossible to study the effect of the drug in total concentrations higher than 1 in 100. From the table given below, it will be seen that even as high a concentration as 1 in 100 does not at all affect the growth of the organisms.

In the case of Stibosan, in a strength of 1 in 20 the organisms were quite active after 3 hours 14 minutes.

Experiments were also made to see if berberine sulphate, given in the strengths used in therapeutics produces any local action on the tissues. Intramuscular injections of 1.5 c.c. of a 1 per cent. solution of berberine sulphate were given between the gluteal muscles of cats and rabbits. The animals were killed after 6 and 24 hours. In no case was there any naked eye evidence of inflammation or necrosis.

Pathological examination of the gluteal muscle of a rabbit in which an intramuscular injection of 1.5 c.c. of a 1 per cent. solution of berberine sulphate had been given 24 hours previously, showed that the upper surface of the muscle had dilated vessels. The endothelial cells were large and swollen. There was no leucocytic migration.

TABLE V.

Shows the growth of flagellates obtained after inoculating tubes of N.N.N. medium containing different amounts of Stibosan with L. tropica.

GROWTH +				No GROWTH -		
L. tropica ..	Concentration of Stibosan.					
	1- 100	1- 200	1- 300	1- 400	1- 500	Control.
	+	+	+	+	+	+

Stibosan evidently has no direct action on *L. tropica* whereas berberine sulphate in dilutions as high as 1 in 80,000 definitely inhibits the growth of the parasite.

A comparative study of the behaviour of *L. tropica*, when brought into contact with different strengths of berberine sulphate and Stibosan was made by direct observation under the

The under surface of the same muscle showed a good deal of lymph between the muscular bundles for some depth into the muscle. The endothelial cells were well seen. No leucocytic migration was evident. Berberine sulphate causes simple dilatation of the vessels in the neighbourhood followed by simple oedema. Tissues are not necrosed.

In one rabbit 0.75 c.c. of a 2 per cent. solution of the acid sulphate of berberine was also tried and there was no indication of any inflammation. The drug, therefore, can safely be given in 1 or 2 per cent. solutions hypodermically or intramuscularly. The greater solubility of the acid sulphate makes it possible to give smaller amounts of fluid and minimises the discomfort produced by larger amounts. The actions of the two salts are identical.

Berberine sulphate was also tried clinically in cases of oriental sore and gave very satisfactory results.

Technique.—1 to 2 c.c. of a 1 per cent. solution of the sulphate or 0.5 to 1 c.c. of a 2 per cent solution of the acid sulphate, according to the size of the sore, is injected as follows. The needle is inserted just above the margin of the sore and the solution injected near its edge. Four or more punctures are made so as to infiltrate the sore from all sides. The injections are repeated a week after and as a rule not more than three injections are required to bring about a complete cure. Two injections are often quite sufficient.

The solutions are very stable and can be preserved in sterile tubes with rubber caps, requisite amounts being withdrawn by the syringe whenever required. The treatment is not very painful and does not involve any risk as the injections are given locally. No expert skill is required to give the injections and the treatment can be given in any outlying dispensary by any medical man, the only apparatus required being a simple hypodermic syringe. The drug is very cheap: the approximate cost of the drug required for treating one sore being somewhat less than 3 pice.

Following is a summary of reports of cases treated with berberine sulphate:—

Case No. 1.—B. C. Hindu male, age 13 years.

An ulcer about the size of an eight-anna piece on the forearm. Duration $4\frac{1}{2}$ years. Smear from the edge showed a large number of *L. tropica*.

Six injections of stiburea commencing from 0.05 grm. and rising up to 0.15 grm. were given twice a week, without any improvement in the lesion.

Two injections of berberine sulphate were then given by the infiltration method using 1.5 c.c. of a 1 per cent. solution. The scab fell off leaving a raw surface and the sore was then dressed with ung. zinei for 3 or 4 days. The sore healed up perfectly.

Case No. 2.—Mrs. P. Hindu female, age 32 years.

Lesions.—Two ulcers on fore-head, 1 on cheek, 2 on the back of wrist.

Duration.—The oldest one appeared 8 months back.

Lab. findings.—Parasites present in all lesions.

Each sore was treated with 3 weekly injections of 1.5 c.c. of 1 per cent. solution of berberine sulphate. All healed up within a month.

Case No. 3.—Mr. B. Hindu male, age 50 years.

Lesions.—Three sores on fore-arm. All appeared about the same time.

Lab. findings.—Parasites present in all.

He had 2 injections of berberine sulphate 1.5 c.c. of 1 per cent. solution. Discharged cured.

Case No. 4.—Mr. S. Hindu male, age 45 years.

Lesions.—Two sores on the leg, both chronic, one of 8 years duration, the other about 1 year.

Lab. findings.—Old lesion was negative to leishmania, but scanty bottle bacilli were found.

Culture from the 2nd gave a good growth of flagellates.

The patient had received 22 injections of antimony (no information about the salt and the dose) and the sore was cauterized twice.

Four injections of berberine sulphate were given at weekly intervals. The patient had a good recovery.

Case No 5.—Mrs. S. Hindu female.

Lesion.—A sore on the nose; was treated with mercuric ointment.

Lab. finding.—Leishman's were present. Berberine sulphate injected as before; 2 days after the 1st injection, smear negative; culture after 5 days, negative. One more injection was given and the sore was completely healed.

In case No. 2, material from the lesion on the cheek which had not yet ulcerated was cultured on N.N.N. medium and a rich growth of flagellates was obtained. 0.2 c.c. of water of condensation from 2 tubes of N.N.N. culture medium was injected into the shaved skin of an English mouse. A small nodule was produced showing scanty leishmania. The nodule was then treated with berberine sulphate solution (10 times weaker than that used for human beings). The nodule disappeared within 7 days. The mouse died later of some intercurrent disease.

Conclusions.

(1) Berberine sulphate inhibits the growth of *L. tropica* even in high dilutions like 1 in 80,000. Stibosan has no local action on the parasite. This may be the reason why antimony ointments are useless in the treatment of oriental sore.

(2) Berberine sulphate given by infiltrating the tissues around the edge of the sore, brings about complete cure in 2 or 3 weeks. The drug promises to be a specific cure for oriental sore.

TERMINALIA ARJUNA: ITS CHEMISTRY, PHARMACOLOGY AND THERAPEUTIC ACTION.

By R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

In-charge, Indigenous Drugs Inquiry, Indian Research Fund Association,

and

SUDHAMOY GHOSH, D.Sc., F.R.S.E.

(From the Department of Pharmacology and Chemistry, Calcutta School of Tropical Medicine and Hygiene.)

HISTORY, BOTANY, USES, ETC.

Terminalia arjuna is a large deciduous tree attaining a height of 60 to 80 feet which is common throughout the sub-Himalayan tracts of the United Provinces, and in the Deccan, Southern Bihar, Chota Nagpur, Burma and Ceylon. It is

called "Arjun" in Hindi and Bengali and "Arjuna" in Sanskrit. The bark is $\frac{1}{2}$ inch thick and is considered by the Sanskrit writers to be a cardiac tonic. Chakradatta, the great Hindu physician, described it as tonic, astringent and cooling, and prescribed it in heart disease and for those purposes for which astringents are generally applied. In heart disease he recommended it to be given as a decoction with milk and treacle and water or as a "ghrita" (preparation with "ghee" or melted butter) made with the decoction and powder of the bark.

The bark and preparations made from it are reputed to have a marked action on the heart even to the present day in this country. The "Kabirajes" use them for all sorts of conditions of cardiac failure and dropsy. Some of the practitioners of western medicine believe in its stimulant effect on the heart and use it as cardiac tonic. A liquid extract prepared from the bark is on the market in Calcutta. It was for this reason that we took up investigation of this drug.

CHEMICAL COMPOSITION.

A reference to the literature shows that this drug has interested many previous investigators.

Hooper (1891) mentioned that the bark yields 34 per cent. of ash consisting of almost pure CaCO_3 ; the watery extract contains as much as 23 per cent. of calcium salts and 16 per cent. of tannins. Ghoshal (1909) made a detailed chemical and pharmacological study of the bark. He found it to contain the following substances:— (1) sugar, (2) tannins, (3) a colouring matter, (4) a body of glucosidal nature and (5) carbonates of Ca and Na and traces of chlorides of alkali metals. He also found that the total tannin content amounted to 12 per cent. and the content of ash to 30 per cent.

The present investigation was started in order to determine the active principle which might be responsible for the alleged stimulant action of the drug on the heart. The bark was obtained from a reliable source and was dried in air. As the drug was said to contain glucosides, an enormous amount of careful and laborious work extending over a year was done to prove or disprove their presence. A portion of this work was done by one of us (S. G.) in the Pharmaceutical Institute of Berlin. A brief summary of the work and the procedure adopted is given in the following paragraphs:—

For a systematic examination, about 200 grms. of the powdered bark was carefully weighed out and extracted in a large glass soxhlet for several days with petroleum ether (B. P. 35° – 50° C.). The yield of the petroleum ether extract, freed from the solvent was only 0.13 per cent. It contained no oily matter and when fractionally crystallised from dilute alcohol gave a minute quantity of colourless crystals which gave the reactions of a phytosterol. Nothing else could be isolated from the other fractions.

The residual powder, after extraction with petroleum ether, was extracted with ether for some days until the extraction was complete. The ethereal extract, freed from the solvent, amounted to 0.37 per cent. The substance was recrystallised from ether and some colourless crystals were isolated. The dried crystals softened at 225° and melted with decomposition at 230°C . On testing they were found to be those of an organic acid but the yield was very small. Nothing else was found in the ethereal fraction.

The residual powder, after extraction with ether, was then extracted for several days with absolute alcohol until the extraction was complete. The yield of the absolute alcoholic extract, freed from solvent, amounted to 18.12 per cent. The residue was dark red, brittle and amorphous and gave strong colour reactions for tannins.

To test for alkaloids, a portion of its solution in alcohol was treated with a few drops of acetic acid, the alcohol was removed and the residue taken up in water. The filtered aqueous solution was made slightly alkaline with Na_2CO_3 and shaken with ether and CHCl_3 . No alkaloid could be thus traced in the alcoholic extract.

The alcoholic extract was soluble in acetone, hardly so in acetic ester and chloroform and partially soluble in amyl alcohol. A separation of the constituent tannins and colouring matters was attempted by fractional precipitation with different organic solvents but no satisfactory separation could be effected.

To determine the nature of the tannins, an aqueous solution was tested with various reagents. With FeCl_3 it gave a bluish-black precipitate. When poured into a solution of KOH , it gave a deep red colour. With concentrated H_2SO_4 , a few drops of the solution gave a red colour. With a solution of iron alum it gave an olive colour and on adding some solid sodium acetate there was a bluish black colour. 50 c.c. of the original solution and 25 c.c. of a mixture of HCl and formalin (100 c.c. of concentrated HCl , 100 c.c. water and 150 c.c. of 40 per cent. formaldehyde) were boiled under reflux for $\frac{1}{2}$ hour. A precipitate was obtained showing the presence of pyrocatechol tannins. The filtrate gave with iron alum and solid sodium acetate a bluish black colour. With bromine water the original solution gave a precipitate. A portion of the solid alcoholic extract was fused with KOH and the melt dissolved in water, filtered, acidified with dilute H_2SO_4 , filtered and extracted with ether. The residue from ether was decolourised in alcoholic solution with animal charcoal and the filtrate evaporated to dryness. The residue dissolved in water gave a green colour with FeCl_3 which was turned red with Na_2CO_3 and with Na -acetate; with Br_2 water it gave a reddish brown colour. (1928) principles.

All these reactions show that the tannin in the arjun bark is mainly a pyrocatechol tannin.

An attempt was also made to determine if any substance of glucosidic nature could be separated. The alcoholic extract was dissolved in hot water and treated with lead acetate and basic lead acetate. The filtrate was freed from lead by H_2S and concentrated *in vacuo* to a small bulk. The concentrated solution was filtered and evaporated to dryness in a vacuum desiccator over H_2SO_4 . Nothing separated out during the evaporation over H_2SO_4 . The residue was taken up in absolute alcohol and filtered. The filtrate was concentrated to a small bulk, treated with excess of chloroform and filtered. The filtrate was evaporated to dryness and the residue taken up in water. It did not reduce Fehling's solution. On hydrolysis with HCl , a white precipitate was obtained but the hydrolysed product did not reduce Fehling's solution.

As the amount of the above substance was too small for further work, a large quantity of the bark was extracted with alcohol. The alcohol was recovered and the residual powder dissolved in hot water. To avoid the presence of acetates for pharmacological trials, the aqueous solution was treated with excess of lead hydroxide (freshly precipitated and washed free from soluble salts). The filtrate was freed from Pb by H_2S and the filtered solution concentrated *in vacuo* to a small bulk. The filtered liquid was finally evaporated to dryness *in vacuo* over H_2SO_4 and treated in the above way. The residue was optically inactive. It was easily hydrolysed by HCl but the hydrolysed solution was also inactive. It did not reduce Fehling's solution either before or after hydrolysis. It was also found to be pharmacologically inactive. It was, therefore, not a glucoside but probably an ester-like compound.

The original bark, extracted with petroleum ether, ether and absolute alcohol, was next extracted 5 times with large bulks of boiling water. The aqueous filtrates were concentrated *in vacuo* to a very small bulk and precipitated by a large bulk of alcohol.

The precipitate was dried in a desiccator. When burned it gave a large amount of ash. It probably consisted of inorganic salts and salts of organic acids and was not deemed of pharmacological interest. The ash showed the presence of Al, Mg and large quantities of Ca.

The filtrate, freed from alcohol, was precipitated by lead acetate and then by basic lead acetate, the filtrate being freed from Pb and concentrated *in vacuo*. It showed the presence of only sugars. The lead acetate and basic lead acetate precipitates, which were small, were also tested separately but nothing of any interest could be detected. 100 grams of the arjun bark was then tested for glucosides by Bour's process by the use of the pure curve showing the absence of glucose (including tannins and colouring matters).

Estimation of tannins.—

(1) Hyde powder method: Schroder's process was used and gave 11.21 per cent. of tannins.

(2) Blood method: The hæmolytic process of Brandt was followed using fresh ox blood collected from a slaughter house. The first series of experiments gave the limit between 10 and 20 per cent. and the second series, with higher dilution, gave the final value at 12 per cent. (The method is described as approximate but comparable.)

An estimation by the Pb method was also carried out as a control to see the upper limit. The value obtained was 15 per cent. (It is generally high, since lead acetate precipitates not only the tannins but also the colouring matters and some other substances.)

The result of the chemical analysis may be summarised as follows:—

(1) About 12 per cent. of tannins, consisting mainly of pyrocatechol tannins.

(2) Some colouring matters.

(3) An organic acid with a high melting point and a phytosterol.

(4) An organic ester easily hydrolysed by mineral acids.

(5) Large amounts of calcium salts with smaller amounts of Al and Mg salts.

(6) Sugar, etc.

Pharmacological Action.—It will be seen that analysis of the bark of *Terminalia arjuna* does not reveal the presence of active principles which could account for its cardiac tonic effects, which are so widely believed in in this country. We carefully tested the different fractions obtained from petroleum ether, alcoholic and aqueous extracts during analysis, but found that with the exception of calcium compounds, no other constituent produced any effect on the heart or on any of the other tissues. The colouring matter was separated and tested with the same result. It will be seen, therefore, that we could not detect any pharmacologically active bodies in the bark of *Terminalia arjuna* either by chemical or biological methods.

Clinical Trials.—An alcoholic extract was prepared from the bark in our laboratory. It was carefully tested in a number of patients suffering from failure of cardiac compensation with or without dropsy. In none of the patients the drug did produce any marked effects such as are produced by drugs of the digitalis or caffein groups. The rate, frequency, force of the heart beat and the blood pressure remained appreciably unaltered. The secretion of urine was not markedly affected in these cases. Any therapeutic effects attributed to the drug may be accounted for by the high calcium content to which reference has already been made.

Summary and conclusions.

(1) An analysis of the bark of *Terminalia arjuna* does not reveal the presence of any active principles of the nature of alkaloid, glucoside or essential oil. With the exception of large amounts of calcium salts, tannins, organic acids, an organic ester and sugars no other substances could be detected.

(2) Different fractions obtained during the course of analysis from the bark including the petroleum ether, alcoholic and aqueous extracts and colouring matter were found not to show any marked physiological activity.

(3) An alcoholic extract prepared from the bark was tried in a number of patients suffering from cardiac decompensation but it did not show any appreciable effects such as are produced with the cardiac tonic drugs of the British Pharmacopœia.

A PRELIMINARY NOTE ON THE ACTION OF VASOPRESSIN AND OXYTOCIN.*

By J. CHRISTODOSS DAVID, M.B., B.S.,
Professor of Pharmacology,
and

C. VAREED, M.B., B.S.,
Demonstrator in Pharmacology.

(From the Department of Pharmacology,
Madras Medical College.)

THE physiological properties of extracts of the posterior lobe of the pituitary body are well known. Briefly, they cause marked vaso-constriction and raise the blood pressure; they stimulate uterine contractions and are also diuretics. As opposed to this last observation, they markedly reduce the secretion of urine in the disease called diabetes insipidus. But chemical information regarding the physiologically active constituents of pituitary extracts is very meagre. Much controversy has raged round the question, whether these various physiological activities are due to one hormone or to more than one active principle. The general conclusion that can be drawn, from the work that has been done, is that the physiological activity of extracts of the posterior lobe of the pituitary body is due chiefly to two active principles, one tending to cause a rise of blood pressure and the other having a specific oxytocic action. According to Schafer, the principle which acts upon intestinal muscle differs from the above two and there is little doubt that it is histamine. It is probably histamine that is also responsible for the primary fall of blood pressure observed in some samples. Such samples of the extract as do not exhibit this phenomenon have little action on the intestinal muscle.

Recently O. Kamm and his associates (1928) working in the research laboratory of Parke Davis & Co. have succeeded not only in demonstrating the presence of the two important active principles but they have also been able to separate these two and concentrate them in the form of potent solid preparations. They have shown that solutions of these separated active principles can be recombined to form a pituitary extract identical with the original from

which they were prepared, thus proving that no decomposition has taken place. Both active principles are said to be basic bodies, presumably amines; practical manufacturing methods have been developed for the separation of these two hormones and these have been made available for experimental and clinical study. The oxytocic principle named *a-hypophamine* is put up in ampoules and designated *oxytocin*. The pressor principle or *b-hypophamine* has been labelled *vasopressin*. There is at present only one official standard for extracts of the posterior lobe of the pituitary gland and this is based upon the oxytocic test as described in the U. S. P. The amount of activity contained in 1 c.cm. of the official extract has been designated "10 international units." When extracts are prepared from a good grade of gland there is a fairly constant relation between the amount of oxytocic and pressor activities. So the original workers have designated the amount of pressor activity in 1 c.cm. of the official extract as "10 pressor units." Ordinary pituitrin as marketed for obstetrical purposes, therefore, contains 10 oxytocic units and 10 pressor units per c.cm. Pituitrin as marketed for surgical purposes contains 20 oxytocic units and 20 pressor units. The oxytocin put up for experimental work is said to assay 10 oxytocic activity per c.cm. but its pressor activity is only $\frac{1}{2}$ a unit per c.cm. It is claimed that vasopressin contains 20 pressor units per c.cm. Its oxytocic activity is less than one unit per c.cm. From the results shown above, these authors claim that the purified active principles are bound to have a wider range of clinical use.

These active principles have been subjected to a more complete physiological study by J. H. Gaddum (1928). According to him, oxytocin has, in addition to its action on the uterus, a depressor (blood pressure) action on the fowl and, in certain circumstances, on the cat. Vasopressin, in addition to its effects on the blood pressure and on the kidney (diuresis), has a specific stimulant action on the bowel of the rabbit and a dilator action on the melanophores of the frog; the latter effect is apparently due to a different principle, so that vasopressin is not yet a physiologically pure preparation. A. W. Bourne and J. H. Burn (1928) examined the action of the separated constituents of pituitary extract on the human uterus in labour. They found that oxytocin possesses the typical stimulant action whereas vasopressin has no effect even in large doses. A given dose of oxytocin (2 units) was found to produce a large response in one patient and a small one in another. Discussing the rare cases of pituitary shock which have led to a disinclination on the part of some obstetricians to use pituitary extract, they recommend that oxytocin, having none of the vasomotor effects which are responsible for the collapse, may be confidently used. F. R. Curtis and J. W. Pickering (1928) studied the effect of these active principles on the blood. According to them, vasopressin increases the coagulability of blood both in fasting

*Messrs. Parke Davis & Co., have now changed these names to Petressin and Pitocin respectively.

animals and in those at the height of digestion. After severe hæmorrhage, vasopressin either has no augmentary effect or delays the coagulability of blood. Oxytocin, when intravenously injected into cats increases the clotting time of blood. The injection of oxytocin after hæmorrhage produces increased coagulability. The failure of vasopressin to increase coagulability of blood after hæmorrhage decreases its hæmostatic value. The ability of oxytocin to convert hypo-coagulability into hyper-coagulability after hæmorrhage should be of considerable advantage during and after labour, when the contractile action of oxytocin on the uterus is supplemented by more rapid clotting of the blood with hardly any increase of blood pressure.

We have, at the outset, to thank Messrs. Parke Davis & Co. for supplying us with two boxes of vasopressin and oxytocin for experimental work. It was our desire to examine and see if we could substantiate the claims made for these two active principles. But as the supply was very

with a standard brand of pituitrin available on the market. As in our previous experiments we had invariably obtained better results with P. D. & Co.'s pituitrin, we used a potent sample of this as standard for comparison. Our experiments were done on cats and guinea-pigs. In order to observe the action of these substances in the intact animals, we used pithed cats, in which the medulla was completely destroyed by passing a convenient sharp instrument through the foramen magnum.

The blood pressure tracings were recorded as usual and the uterine graphs were obtained by Barbour's method as modified by Chopra and David (1927). Injections were given at intervals of one hour allowing sufficient time for the effects of the previous injection to pass away. The action on the isolated guinea-pig's uterus was studied by means of Dale's uterine bath.

Fig. 1 shows the effect of intravenous injections of the active principles on the blood pressure and uterine movements of a pithed cat

Fig. 1.

(b)

(c)

limited our observations be restricted.

Our method was to compare the

ns also had necessarily to

assay these two substances to get their toxic and pressor values

0.05 c.cm. doses of pituitrin and vasopressin produce the same rise of blood pressure. 0.05 c.cm. of oxytocin and the same dose of pituitrin cause the same height of uterine contraction. With

vasopressin, generally only a slight contraction of the uterus is noticed or there may be no effect at all. But when the uterus is unusually irritable as in pregnancy, an appreciable contraction has been noticed. The character of the contraction is not identical with what is obtained either with pituitrin or oxytocin. While with the latter there is an immediate and steadily increasing tonic contraction, in the case of vasopressin the organ relaxes between contractions exhibiting a "staircase phenomenon." After the full height of contraction is reached the uterus relaxes quickly even before the bath is washed out.

Fig. 2 shows the effect on the isolated non-pregnant uterus of the guinea-pig. 1 in 3000 dilutions (0.05 c.cm. in 150 c.cm.) of oxytocin and

pituitrin generally produce the same height of contraction, while an identical dose of vasopressin either produces no effect at all or only a slight contraction or just an increase of the automatic movements.

0.25 c.cm. vasopressin, i.e., a dilution of 1 in 600 in the bath, exhibits about the same oxytotic activity as 0.01 c.cm. of pituitrin, i.e., 1 in 15,000 dilution. This indicates that the oxytotic activity of vasopressin is about 4 per cent. of that of pituitrin (Fig. 3 a and b).

Intravenous injection into a pithed cat of 0.5 cc. of oxytocin causes about the same rise of blood pressure as 0.025 c.cm. of pituitrin; showing that oxytocin has about 5 per cent. pressor activity as compared with pituitrin (Fig. 3 c and d).

Fig. 2.

(c)

(d)

Summary and Conclusion.

(1) The action on the blood pressure and uterine contractions of the separated active principles of the posterior lobe of the pituitary gland, designated *vasopressin* and *oxytocin* been studied.

(2) While the pressor activity of vasopressin equals that contained in the same quantity of pituitrin, its oxytotic value is only about 4 per cent.

(3) The oxytotic action of oxytocin is about the same as that of pituitrin; but its pressor activity assays only about 5 per cent.

(4) The results obtained by us, as well as by previous workers, indicate that oxytocin is a valuable substitute for the whole extract in obstetric cases especially where a rise of blood pressure is undesirable, as in eclampsia.

THE HISTORY OF TICK-BITES IN CASES OF TICK-TYPHUS IN INDIA.

By S. SUNDAR RAO.

(From the Calcutta School of Tropical Medicine.)

CASES of tick-typus are sporadic in occurrence in India and are usually found distributed in hilly tracts with forests or jungle close by. The localities in which cases of typical tick-typus have occurred are:—Sat Tal (Kumaon), Narayangunj (Dacca), Balaghat (C. P.), Bangalore (Mysore), Malakand (N. W. Frontier) and Kalimpong (Darjeeling).

The characteristics of tick-typus as distinguished from other allied fevers have been discussed by Megaw and Rao (1928). Out of the cases discussed in that paper, eight cases of tick-typus gave a definite history of tick-bite, while in nearly all the other cases the circumstances were such that there was a great probability of a tick-bite which was apparently not noticed by the victim. In several instances the attacks started some days after a visit to the forests or jungle close by, or under circumstances where a tick-bite was very likely. A few of the cases totally denied any history of a tick-bite, but even in such cases, one cannot be too sure that they were not bitten by ticks. Tick-bite is easily overlooked, because of the perfectly un irritating and painless manner in which the tick attacks man. That ticks can stay on man without the victim noticing them for prolonged periods is quite possible. Two instances are described in this article where the presence of attached ticks on the person of two naturalists was not observed by them for long periods. As this has

happened to people with full knowledge of the habits of ticks, and who took particular precautions to avoid tick-bites, it is easily understood how likely it is that tick-bites are overlooked by lay persons.

Mr. S., a geologist, went to Assam in connection with his professional work, in December 1923, and had occasion to go into the forests in the district of Sylhet. He stayed there for a few days, and then returned to Calcutta. Seventeen days after his return to Calcutta, he reported the presence of a tick on his person on the left side of the lower abdomen. I found the tick almost completely imbedded in the skin, and only the posterior portion was seen from outside. The skin around the tick-bite had become swollen and indurated and had almost hidden the tick from view. The tick was extracted and in the region of the bite was a very large induration over an inch in diameter. No identification of the specimen was made as it was unfortunately lost.

The point of interest in this case is that this geologist, who knows what a tick is like, was not aware of the presence of the tick on his body for a period of over seventeen days, although he had a bath with soap and hot water every day.

Mr. I., an entomologist, in 1928 went into the Sukna forests in the Darjeeling Terai to collect insects. After every visit into the forests, he took care to collect all ticks on his clothing and body, and had a bath with plenty of soap, a procedure followed by the local people to get rid of ticks; Mr. I. took every care to get rid of ticks on his person, and, being an entomologist himself, knew how to do it.

Eight days after he returned to Calcutta, he felt a scab sticking to his body on the left side of the lower abdomen. On examination it was found to be a tick, which had half buried itself in the body. There was no pain at the site of the bite, and there was a hard induration, half an inch in diameter. After very hard pulling at the tick, only the body of the tick came off, the mouth-parts being left inside. The writer subsequently extracted the mouth-parts of the tick by cutting into the tissues with a Hagedorn needle and after a good deal of dissection. Even then it was found that the apical half of the right mandibular sheath and right mandible were broken and left within the tissue. The photo-micrograph reproduced here (Fig. 1) is of the mouth-parts extracted from the body of the victim. The tick has been identified as the nymphal stage of *Rhipicephalus hamaphysaloides* Supino.

Two points of interest arise out of the present instances.

Sufferers from typical tick-typus have frequently asserted that they have had no history of tick-bite. Such cases are easily understood in view of the present instance. Here a specialist in entomology had not observed the presence of a tick on his body for a period of over eight days, although he had made a search for them on his person and had a bath every day. When under such conditions the tick had escaped notice,

it is conceivable how easy it is for lay persons to overlook the presence of a tick. The writer

Fig. 1.

Micro-photograph of the mouth-parts of tick extracted from Mr. I.; Nymphal stage of *Rhipicephalus hamaphysaloides* Supino.

suggests that in cases of tick-typhus, besides enquiring into the possibility of a tick-bite, a thorough examination should be made for the presence of either a tick, or an area of induration.

The second point of interest is that while going through a forest, a very large number of ticks get to one's clothing. Yet most of them would not attack man. In one instance, over fifty specimens of ticks were collected from an individual who had been in the forests at Sukna, and these ticks were mostly of the species *Hamaphysalis bispinosa*, whilst only one of them was *Rhipicephalus hamaphysaloides*. While the former species do not attack man, and after some time drop off, the latter attack man.

Summary.

(1) In cases of tick-typhus the denial of a history of tick-bite by the patient cannot be relied upon. When naturalists acquainted with ticks had failed to observe the presence of ticks on their person for long periods, lay persons are easily liable to overlook the presence of ticks on their body. A thorough examination, therefore, of the patient for ticks or induration caused by tick-bites is necessary.

(2) Not all ticks, that get on to man while out in the forest attack him; some species attack, others drop off. *Rhipicephalus hamaphysaloides* has been found to attack man in the Darjeeling Terai; while *Hamaphysalis bispinosa*, which is far more numerous, does not do so.

The writer is indebted to Mr. M. Sharii, Assistant, Superintendent, Zoological Survey of India, for his kindness in determining the specimens sent to him.

INTRAVENOUS CALCIUM THERAPY.

By S. RAMA IYER, L.M. & S. (Mad.), V.H.A.S.,
Civil Surgeon, Thaton.

On page 485 of the *Indian Medical Gazette* for August, 1928, an extract on the danger of intravenous calcium therapy from the *British Medical Journal* (April, 21, 1928, p. 662) is reproduced, giving an account of two experiments, one in which 50 c.cm. of 1 per cent. solution of calcium chloride and one in which 4 c.cm. of a 10 per cent. calcium chloride solution was injected intravenously. It is said that in the second experiment syncope and respiratory failure, and signs of sino-auricular heart block were caused and it was thought inadvisable to repeat the experiment following atropinization.

It is not clear from the aforesaid extract whether the calcium chloride solution used for intravenous injection was merely the solution of calcium chloride in distilled water or the solution made with physiological salt solution.

I have since 1924 been using 7.5 per cent. calcium chloride solution, prepared as described below, for intravenous injection of patients, particularly those suffering from orchitis due to gonorrhœa and also in other cases where calcium therapy is indicated. I have had no mishap. The only symptom of importance noticed was the sense of heat all over the body lasting in all for a couple of minutes or so during and after the injection. The patients were in all cases able to walk about in five minutes and some were even able to walk back to their houses varying in distance from $\frac{1}{2}$ to $1\frac{1}{2}$ miles. Although I have been unable to explain the cause, the injection brings about in less than 24 hours marvellous reduction in pain and size of the testicular swelling due to gonorrhœal attack particularly when the affection is recent.

The same results I have noticed in the case of epididymitis due to gonorrhœa even of long duration. In other cases where calcium therapy was indicated results by this method were not so striking as in the case of gonorrhœal orchitis or epididymitis. The injections have, however, had no effect on the urethral discharge.

A statement of cases where calcium chloride was injected intravenously from November 1926 to the middle of September 1928 is appended. Cases done before are not included since regular records of them were not kept.

My thanks are due to my Assistant, Mr. C. Basanth Rai for carefully recording the notes for me and also carrying out most of the injections according to my instructions.

The solution used for intravenous injections was prepared and used as follows:—

Calcium chloride	...	5ii.
Aqua distillata	...	5i.

Mix—and keep it as a stock solution.

Take some of this in a clean test tube and boil it; draw 2 c.cm. of it into a sterile 10 c.cm. syringe and draw into it normal saline solution freshly boiled and kept ready in another clean

test tube, up to 7 c.cm. Inject the solution thus diluted into the vein selected. I always see that the test tubes used for this purpose are not used for any other purpose.

Statement of Cases where Calcium Chloride Injections were given at the Civil Hospital, Thaton.

Serial No.	Patients admission No.	Age.	Sex.	Admission date	Prominent signs and symptoms in brief.	Number of injections.	REMARKS.
1	835	30	M	20-11-26	Pain and enlargement of testicles. Duration—one month, cause—not definitely known.	1	Pain relieved but patient absconded.
2	68	24	M	30-1-27	Gonorrhœal discharge of pus from the urethra. Greatly enlarged and painful left testicle. Duration—two months.	2	Had also urethral irrigation with Condy's lotion 1 in 5000. No local treatment to the testicle. Result :—Enlargement of testicle, and pain both disappeared.
3	200	23	M	8-4-27	Had gonorrhœa 6 months ago. Pain in the left testicle with considerable enlargement of it.	1	Pain relieved but patient absconded.
4	552	15	F	8-9-27	Spastic contractions of muscles of lower limbs and inability to walk and other hysterical symptoms.	3	Relieved.
5	592	40	M	1-10-27	Severe fever and plenty of pus from the gums in spite of taking out many teeth; lower jaw also affected.	2	No change.
6	597	19	M	4-10-27	Enlargement of the right testicle with cyst formation. Cause—unknown.	1	No change.
7	777	37	M	22-12-27	Muscular rheumatism, loss of memory; history of syphilis incipient G. P. I.	2	No change.
8	78	28	M	5-2-28	Gonorrhœal discharge of pus from urethra. Pain and enlargement of the right testicle. Duration—one month.	2	Had also urethral irrigations with Condy's lotion 1 in 5000. No local treatment to testicles. Result :—Pain disappeared, enlargement reduced; discharge stopped.
9	176	25	M	25-3-28	Pain and enlargement of the right testicle of 7 days' duration with gonorrhœal discharge of pus from the urethra.	5	Had also urethral irrigation with Condy's lotion 1 in 5000. No local treatment to the testicle. Result :—Pain and swelling completely disappeared.
10	149	19	M.	13-3-28	History of trauma. Right testicle enlarged and painful;	4	No change.
11	214	28	M.	19-2-28	History of gonorrhœa 10 years ago. Pain and enlargement of the right testicle, blood to W. R. +.	8	Pain and enlargement completely disappeared. Salvarsan not injected, since blood result was awaited.
12	O. P.	30	M.	19-2-28	Gonorrhœa 3 months ago; acute pain and enlargement of the right testicle.	1	Pain and swelling reduced.
13	O. P.	35	M.	13-8-28	History of gonorrhœa, pain and enlargement of the testicles with blood + to W. R.	3	Enlargement and pain completely disappeared. Salvarsan not injected since blood result was awaited.
14	507	30	M.	19-6-28	Dysentery with pain in the soles of the feet.	2	No effect on pain in the soles.
15	403	26	M.	16-7-28	Continued fever of over one month, unbearable tingling pain in the feet, legs and hands and forearms.	3	Had also two injections of sodii salicylas Result :—Tingling disappeared.
16	395	30	M.	10-7-28	Gonorrhœal discharge of pus from the urethra; pain and enlargement of the left testicle.	3	Had also bladder wash with Condy's solution 1 in 5000. No local treatment to the testicle. Result :—Testicular pain and enlargement disappeared. No change in testicular pain was noticed by merely washing the bladder with Condy's fluid.

N.B.—The interval between two injections was 4 days except in a few cases where the patients did not attend the hospital regularly for the injections.

SOME SOURCES OF VITAMIN C IN INDIA.

PART I.

The Antiscorbutic Properties of Vegetable Marrow [Lagenaria Vulgaris (Serringe)] Melon Pumpkin or Mitha Kaddu (Cucurbita Moschata) and Pumpkin [Cucurbita Pepo (Linn)].

By R. C. WATS, M.D. (L'pool), D.P.H., D.T.M.,
CAPTAIN, I.M.S.

THE tendency of the regimental contractors to supply repeatedly the above vegetables in summer when other vegetables are scarce and costly is well known. This enquiry was undertaken to judge the vitamin C value of the above vegetables and to ascertain whether the quantities issued as rations were adequate. The scope of the experiments was limited to determining the antiscorbutic properties of the above vegetables in a diet scale such as that exemplified in the Army rations; hence guinea-pigs were fed on the basal

protected the animals from developing scurvy, one set of animals were given the basal diet consisting of oatmeal and 60 c.cs. of autoclaved "rich" milk.

The eighteen experimental guinea-pigs of weights varying between 571 and 815 grammes were divided into the following groups:—

Group No. I, Control.—(a) Two animals, one having the basal diet containing 60 c.cs. of "standard" milk and the other with the same amount of "rich" milk. (b) Two animals on ordinary laboratory diet consisting of lucern, bran, etc.

Group No. II, Vegetable Marrow Series.—(i) Three animals on basal diet containing 60 c.cs. heated "standard" milk with 5, 10 and 15 grammes of the cooked vegetable respectively.

(ii) Three animals on basal diet containing 60 c.cs. heated "rich" milk with 5, 10 and 15 grammes of cooked vegetable respectively.

Group No. III, Sweet Kaddu Series.—Same as Group No. II except for the substitution of 5 and

diet and cooked vegetables and no attempt was made to test the efficacy of the raw materials.

Guinea-pigs were selected for the experiments, on account of their well-known susceptibility to scurvy. They were all given a basal diet of oatmeal, bran and 60 c.cs. of heated milk (autoclaved for 1½ hours at 115°C.). The milk used was obtained from the Government Dairy Farm and was standardised to contain 3 per cent. fat (referred to hereafter as standard milk). The respective vegetables were peeled, as in the regimental cook-houses and boiled for 20 minutes in "salted" water before administration to animals. To determine to what extent the presence of "rich" milk containing 5 to 7 per cent. of milk fats (referred to below as rich milk)

10 grammes of cooked sweet kaddu.

Group No. IV, Pumpkin Series.—Same as above except for the substitution of 5 and 10 grammes of cooked pumpkin.

In the case of Control animals (Group No. I(a)), the one on "rich" milk steadily lost weight and died on the 33rd day of the experiment,—the other lost weight until the 14th day and then began to increase in weight but died all the same on the 39th day. Both animals showed signs of scurvy at autopsy, i.e., hæmorrhages in various parts (intestines, bladder, kidney, costochondral junctions, etc.).

The two animals of Group I (b) increased and decreased steadily in weight as seen in the graph.

Group No. II, Vegetable Marrow Series.—(i) Out of the three animals having "standard" milk in the basal diet, the one having 5 grammes of the vegetable kept losing weight until the 20th day, then gained some for a few days but lost again and died on the 43rd day. The animal having 10 grammes of the vegetable gradually lost weight and died on the 34th day. Both animals had the usual signs of scurvy at autopsy. The animal having 15 grammes of marrow in the diet steadily increased until the

ones, and went on losing weight until its death on the 49th day. The other animal having 10 grammes of pumpkin went on gaining weight until the 68th day when the experiment was terminated.

(ii) The animal on "rich" milk diet having 5 grammes of the vegetable died on the 54th* day and the one having 10 grammes on the 45th day. The animals on rich milk diet with 10 grammes of pumpkin and 15 grammes of vegetable marrow showed the following symptoms on

30th day and then decreased to some extent but was living at the end of the experiment.

(ii) The animals having "rich" milk basal diet with 5, 10 and 15 grammes of marrow gradually put on weight except during the last one or two weeks but died all the same on the 36th, 39th and 66th day, respectively.

Group No. III, Sweet Kaddu Series.—(i) Out of the two animals having "standard" milk in their basal diet, the one having 5 grammes of the vegetable put on weight until the 26th day, lost weight during the following week and died. The one having 10 grammes of the vegetable went on gaining weight until the 68th day and showed no apparent signs of scurvy.

(ii) Of the two animals which were given basal diet supplemented by "rich" milk, one having 5 grammes of the vegetable increased in weight steadily except during the last few days, but died on the 33rd day. The one having 10 grammes of the vegetable lost weight gradually with some intervening rises in the weight curve and died on the 51st day.

Group No. IV, Pumpkin Series.—(i) The animal having 5 grammes of the vegetable with "standard" milk basal diet cannot be compared with the other as the former proved to be pregnant, hence the rapid increase in weight curve. It delivered on the 33rd day two still-born young

the 40th and 45th day, respectively. The movement of the hind limbs seemed to be painful, hence

*The figures given in the text do not in some instances correspond with the graphs in the charts.—
Ed., I. M. G.

the reluctance of the animal to move about when released from the cage. On pressure the muscles of the hind legs seemed to be tender and to some extent insensitive to pinpricks. There seemed to be some difficulty in defaecation, the stool pellets getting accumulated in the anus but not being expelled for a long time.

The results of all post-mortem examinations are recorded in the details of the experiments given at the end of the paper, which prove that death in all cases, except one, was due to scurvy (see under "Summary").

SUMMARY.

I. The antiscorbutic values of the vegetables under experiment and their practical application.

The results of the group of experiments, in which the basal diet was supplemented by "standard" milk (3 per cent. milk fat), go to prove that 15 grammes of vegetable marrow and 10 grammes of pumpkin and melon pumpkin are capable of protecting guinea-pigs from scurvy.

Veddar(1) discussing the physiological action of the vitamins mentions that while a human being requires an ounce of lime juice, the guinea-pig requires about one-tenth (3 c.c.s.) in its daily diet to prevent scurvy. If the same ratio was to hold good in the case of other materials containing vitamin C then 100 grammes or $3\frac{1}{2}$ oz. nett of pumpkin or *mitha kaddu* (melon pumpkin) will be required per day per man. As a result of several weighings it was found, during the course of these experiments, that 50 per cent. of these vegetables were thrown away during the process of peeling by the cooks. This observation was made in a cook-house for British troops by weighing the vegetables before and after they were ready for cooking. Keeping this in mind, it can safely be concluded that at least 6 ozs. of pumpkin or melon pumpkin (when no other source of vitamin C is available) will be required daily to act as an antiscorbutic for human beings. Vegetable marrow is poor in antiscorbutic properties and the large amount

(over 5 ozs. nett) required will be too bulky for any one to consume with relish. At present the ration scale for British troops (2) allows an issue of 8 ozs. of vegetables (other than potatoes and onions), 6 ozs. of onions and 10 ozs. of potatoes. If we take the combined value of these components (potatoes and onions alone being ample for the purpose), it will be evident that the amount of vitamin C available will be liberal even if the "vegetable" issued is vegetable marrow.

II. The effect of "rich" milk (fat over 5 per cent.) in the basal diet used in the above experiments.

In the following description S.M.D. stands for basal diet with "standard" milk and R.M.D. for the one with "rich" milk.

1. Among the control animals the one on R.M.D. died a week earlier than the other (S.M.D.).

2. Among the animals having 5 grammes of vegetable marrow the one on R.M.D. died a week earlier than the other, while out of those having 10 grammes of this vegetable the reverse held good, viz., the one on S.M.D. died 5 days earlier than the one on R.M.D. The animal on R.M.D. and 15 grammes of the vegetable showed symptoms of (?) neuritis in the hind legs (see above) while the other on S.M.D. was normal. The hæmorrhages seen post-mortem in the animals were absent in the former and no other signs of scurvy were seen.

3. In the melon pumpkin group both animals on R.M.D. having 5 and 10 grammes of the vegetable died earlier than the others (S.M.D.), the difference being 4 and 44 days, respectively. The animals on S.M.D. and 10 grammes of this vegetable were putting on weight and showing

no signs of scurvy on termination of the experiment on the 68th day.

4. Among the animals of Group IV (pumpkin), only those having 10 grammes of the vegetable could be compared, as the one on S.M.D. and 5 grammes of this vegetable was found to be pregnant and died 5 days earlier than the other (R.M.D.). Out of the two having 10 grammes of the vegetable, the one on R.M.D. died on the 45th day, while the other (S.M.D.) gained in

weight and showed no signs of scurvy on termination of the experiments on the 68th day. The former animal (on R.M.D.) showed the abnormalities referred to under paragraph 3 above but signs of scurvy were well marked post-mortem.

No definite inference can be drawn as to why the animals fed on "rich" milk diet died more rapidly than those on "standard" milk. This much is evident that the "rich" diet did not prevent the onset of scurvy though it did prevent the falling of the body weight in some cases. McCarrison(3), discussing the factors influencing the onset of deficiency disease, lays stress on the balance of proteins, carbohydrates and fats; it may be the disproportionate richness of milk fats in the present case which expedited the onset of scurvy and death. Hopkins(4), discussing polyneuritis in birds, states that in the absence of vitamin B, vitamin A may exert an actually harmful influence—the same may probably be true in case of the deficiency of vitamin C. It was presumed before the beginning of these experiments that the rich milk containing, as it does, an extra amount of vitamin A and milk fats would postpone—if not prevent,—the onset of scurvy but the contrary happened and vitamin A did not act as a complementary to or co-operative with vitamin C. It may be stated here that no signs of gastro-intestinal disturbance, except temporary anorexia in some cases, were noted in any of the guinea-pigs.

The animals on rich milk diet with 10 and 15 grammes of vegetable marrow and pumpkin, respectively, had nervous symptoms in the hind legs. The absence of any signs or symptoms of scurvy and the presence of (?) neuritis seen in the animal having 15 grammes of marrow seems to point more towards beri-beri than scurvy, while the animal on 10 grammes of pumpkin showed a combination of both the deficiency diseases. It may be added that no sub-periosteal hæmorrhages were seen in the long bones of the hind limbs.

PART II.

Whatever view may be held as to the exact causation of scurvy, all experience goes to show that the administration of fresh lemon or lime juice is a therapeutical measure of the first order—the former supposed to be four times as potent as the latter. It is not commonly known that lemon (*Citrus lemonum*) exists to a very limited extent in the North West of India and the term "lemon" used commonly is a misnomer. The fruit found ubiquitously throughout India is a lime (*Citrus medica* var *acida*) and not a lemon at all. The following experiments were carried out to determine the vitamin C content of this fruit, as the knowledge might prove useful to those medical men who have to treat cases of scurvy or use the juice as a prophylactic.

As in Part I, the guinea-pigs were put on two kinds of basal diet, one containing rich milk (fat content 5 to 7 per cent.) and the other containing standard milk (fat content 3 per cent.). The animals were divided up as follows:—

- (i) Two animals on basal diet containing 60 c.cs. of heated standard milk with 3 and 5 c.cs. of "lemon" juice.
- (ii) Two animals on basal diet containing 60 c.cs. of heated rich milk with 3 and 5 c.cs. of "lemon" juice.

Both the animals on standard and rich milk basal diet supplemented by 3 c.cs. of "lemon" juice died of scurvy on or about the 64th day. The loss of weight in the one having rich milk diet was much more marked than the other.

Both the animals on 5 c.cs. of lemon juice survived and showed no signs of scurvy.

In view of the above it is apparent that 5 c.cs. of the juice extracted from the common "lemon" are capable of protecting a guinea-pig from scurvy, hence a human being would require about 50 c.cs. (if no other source of vitamin C was available) (*see* Part I, Summary I for calculation of the amount).

APPENDIX.

GROUP No. I CONTROL.

(a) Basal diet only.

Date.	Diet.	WEIGHT OF ANIMALS.		REMARKS.
		Standard milk. (1)	Rich milk. (2)	
27-3-1928 ..	Oatmeal, bran and water <i>ad lib</i> with 60 c.cs. of heated milk.	792 grammes	663 grammes	
2-4-1928 ..		754 "	653 "

28-4-1928 ..		784 "	474 "	(2) Found dead on 29-4-28 morning.
29-4-1928	(1) Found dead in the morning.
5-5-1928	

Post-mortem examination:—

1. Fed with standard milk.—Subcutaneous hæmorrhages over the abdominal wall, subserous intestinal hæmorrhages, suprarenal glands enlarged and hæmorrhagic. Costochondral junctions enlarged and hæmorrhagic.

2. Fed with rich milk.—Showed well marked intestinal subserous hæmorrhages, also in the bladder. Costochondral junctions were enlarged and hæmorrhagic.

(b) The average weight curve of the two animals on normal laboratory diet is shown on the Graph No. I (Control).

Post-mortem examination:—

I. Standard milk.

1. Fed with 5 grammes of vegetable marrow:—Petechial hæmorrhages on the abdomen and thorax were present. Subserous, intestinal, submucous and bladder hæmorrhages were present. Suprarenals were enlarged and hæmorrhagic.

2. Petechial hæmorrhages were not present on the abdomen and thorax otherwise same as above (1). In addition costochondral junctions were enlarged and hæmorrhagic.

GROUP NO. II.

Basal diet with 5, 10 and 15 grammes of vegetable marrow.

			(alive)			

3. Fed with 15 grammes of marrow.—Living when experiment was terminated. No external signs of scurvy.

II. Rich Milk.

4. Fed with 5 grammes of vegetable marrow. Same as standard milk (1), *see above*. Costochondral junctions were also enlarged and hæmorrhagic.

5. Fed with 10 grammes of vegetable marrow. Same as standard milk (1), *see above*.

6. Fed with 15 grammes of vegetable marrow. No hæmorrhages anywhere, teeth firm. Nothing abnormal seen microscopically.

Post-mortem examination:—

I. Standard Milk.

1. Fed with 5 grammes of sweet kaddu. Petechial hæmorrhages on abdomen and thorax, gums swollen and spongy. Subserous hæmorrhages present on liver and intestines. Costochondral junctions swollen and hæmorrhagic. Suprarenals enlarged and congested.

II. Rich Milk.

3. Fed with 5 grammes of sweet kaddu.

Same as (1) except that the costochondral junctions were not swollen or hæmorrhagic.

4. Fed with 10 grammes of sweet kaddu. Same as (1) except no petechial hæmorrhages on abdomen or thorax, no sponginess of gums. Suprarenals enlarged and congested.

Post-mortem examination:—

I. Standard Milk.

1. Fed on 5 grammes of pumpkin. No petechial hæmorrhages. Subserous intestinal hæmorrhages present. Suprarenals enlarged, congested and hæmorrhagic. Costochondral junctions swollen and hæmorrhagic. Gums spongy and swollen.

II. Rich Milk.

3. Fed with 5 grammes of pumpkin. Same as above (1) except that congestion of liver and petechial hæmorrhages were found. Few hæmorrhages of intestines, no sponginess of gums noted.

4. Fed with 10 grammes of pumpkin. Same as above (1) except petechial hæmorrhages present, suprarenals enlarged and congested. Gums not swollen.

GROUP NO. IV.

Basal diet with 5 and 10 grammes of Pumpkin.

Date.	Diet.	WEIGHT OF ANIMALS.				REMARKS.
		Standard milk.		Rich milk.		
		(1) 5 grms. of Pumpkin.	(2) 10 grms. of Pumpkin.	(3) 5 grms. of Pumpkin.	(4) 10 grms. of Pumpkin.	
27-3-28	Oatmeal, bran and water <i>ad lib</i> with 60 c.c.s. of heated milk.	628 grms.	700 grms.	701 grms.	680 grms.	(4) died on 10-5-1928. (1) died on 15-5-1928. (3) died on 20-5-1928.

A Mirror of Hospital Practice.

TWO CASES OF SURGICAL INTEREST.

By MOHD. AJMAL HUSAIN, M.B., B.S.,
Captain, P.C.M.S.,
Medical Officer Canal Dispensary, Rasul. District
Gujrat. Punjab.
MADURA FOOT.

AHMAD, aged 35 years, resident District Gujrat, Punjab, admitted with enormous swelling of the right foot running up to the ankle joint riddled with numerous sinuses discharging profuse offensive pus containing typical mycetoma granules. Duration 12 years, scraped at various hospitals with no lasting improvement. General condition at the time of admission to the hospital markedly toxæmic owing to prolonged septic absorption with enlargement of inguinal glands. Patient much emaciated, anæmic and running hectic temperature.

Bromide mixture and hypodermic injection of morphia with atropine were given an hour or so

before operation to safeguard against surgical shock.

Operation.—Leg amputated at the junction of the middle with the lower third. Patient had good sleep following anæsthesia.

Progress.—Gradual improvement in the general condition of the patient. Temperature came down to normal and the lymphatic glands subsided in a few days time. Wound healed up by first intention.

Observations:

1. Chronicity of the disease.
2. Futility of half-hearted measures once the diagnosis is established, yellow or black mycetoma granules being characteristic.
3. Value of morphia and atropine hypodermically in bad cases likely to suffer from symptoms of surgical shock following general anæsthesia.

FIBRO-SARCOMA OF THE THIGH.

Budha, 20 years, resident Gujrat, Punjab, admitted with a large swelling in the upper and outer part of the right thigh. Duration 6 months. Swelling troublesome on account of its large size and weight causing dragging pain.

On examination it was found to be a tense swelling, fairly movable on the deeper structures, skin adherent to the growth underneath and greatly stretched showing white lines like those seen on the skin over the gravid uterus, blue dilated veins seen running over it in all directions. On palpation, distinct fluctuations were felt deeply with no other signs of inflammation. This was explored twice, first with an ordinary 10 c.cm. Record syringe and later with an hydrocele-tapping trocar and cannula; each time only a few cubic centimetres of

blood-stained fluid were withdrawn with no marked reduction in the size of the swelling.

Operation.—Under chloroform, incision about six inches long over the most prominent part of the swelling; noticed a growth in the substance of the vastus lateralis, the fibres of which were greatly thinned out and were spread over it. In spite of careful dissection the growth could not be removed entire, the capsule being very adherent to the skin. It burst and discharged about 10 to 12 c.cms. of thick blood-stained fluid. This, however, reduced the size of the swelling by only about a third. The rest of the growth was dissected out with some difficulty by separating the fibres of the vastus lateralis. Remnants of the capsule which was very indefinite, were removed carefully. All bleeding points were secured. These were fairly numerous on account of the vascular nature of the growth. The wound was closed by ordinary interrupted sutures. The weight of the growth removed was approximately 5 to 6 lbs. On section, it had the naked-eye appearance of a fibroma with numerous blood vessels in its substance. The capsule was found to be very indistinct and indefinite suggesting malignancy. After about a week the lower half of the wound healed up by first intention while the stitches in the upper part were found markedly stretched. The latter when removed caused considerable gaping of the margins of the wound, about 5 to 6 ozs. of the same blood-stained fluid escaped and the wound was found to be full of sloughs. These sloughs were thoroughly scraped away and the area touched with pure carbolic acid. The wound became healthy gradually and healed up by granulation.

The patient was discharged cured of this trouble, but was readmitted two weeks later complaining of cough, breathlessness and fever. On examination the whole of the left chest was found to be dull on percussion, with loss of breath sounds. The heart was pushed to the right side as far out as the right nipple line.

On exploring the pleural cavity blood-stained fluid similar to that found in the tumour was drawn. On aspirating 13 ounces of this fluid were withdrawn by Potain's aspirator.

Nature of the Fluid.—Thick, blood-stained, with a specific gravity of 1015, containing a large amount of albumin.

All the chest symptoms gradually improved and the patient was about to be discharged in a few days time when he developed signs of accumulation of fluid on the right side. He was advised to get himself aspirated again but he refused and left the hospital.

Points of Interest:

1. Large size of the growth.
2. Presence of large amount of fluid, produced probably by the cystic degeneration of the growth.
3. Its rapid increase in size.
4. Its association with fluid in the pleural cavity.

Conclusions.—Vascularity of the growth, its rapid increase in size and tendency to recurrence are very suggestive of malignancy while the accumulation of fluid in the pleural cavities suggests the presence of secondary growths in the lungs.

MUSCULO-SPIRAL NERVE PARALYSIS FOLLOWING AN INTRAMUSCULAR INJECTION OF QUININE.

By T. SESHACHALAM, M.R.C.S., L.R.C.P.,
Assistant Surgeon, Victoria Hospital, Bangalore.

H. S. V., a boy aged 16 years, was suffering from malaria for which he received three intramuscular injections of quinine elsewhere. The last injection was given in the right arm on 10th May, 1927. The injection was very painful, the arm was swollen during the afternoon and the wrist was powerless and dropped. The case was seen by me on the 20th July, 1927, (70 days after the lesion). The boy refused prolonged treatment at the time, but came back on the 12th September, 1927, (122 days after the lesion). In addition to the wristdrop there was wasting of all the extensor muscles of the forearm, the supinator longus being particularly atrophied. There was no sensory change.

The wrist was fixed in a hyper-extended position in a Robert Jones' cock-up splint. Electric massage to the muscles of the forearm and passive movements to the fingers and wrist were given every day, after removing the splint and supporting the wrist. The wrist was not allowed to hang unsupported during these movements. In about 20 days' time slight power appeared in the muscles. Active movements were encouraged every day in addition to passive movements. About the middle of October the patient was able to hold the wrist with the hand in a plane with the forearm. He was sent home with advice to carry on active movements.

The patient was seen on 20th December, when the following notes were entered:—

"Full voluntary flexion and extension are possible. The supinator longus has developed to its normal size. There is no wristdrop. Splint removed." A letter received from the patient on the 1st February, 1928, says that he is able to use his right hand as well as he did before the injection.

Intramuscular injection of any sort is very safely done in the upper and outer quadrant in the gluteal region or in the substance of the deltoid and not below the level of its insertion. In the case reported above, the injection had evidently been made in the middle of the arm and the quinine solution must have been put around the nerve.

In cases of musculo-spiral paralysis the wrist is fixed in a hyper-extended position in order to relax all the paralysed muscles so that when they regain their power they may act without the mechanical disadvantage of a lengthened muscle.

My thanks are due to Dr. C. Krishnaswami Rao, Physician of the Victoria Hospital, who saw the patient in his out-patient department and referred the case to me.

A CASE OF HYSTERIA (NARCOLEPSY?)

By M. L. KAMATH, B.A., M.D.,
and

P. KUTUMBIAH, B.A., M.B., B.S.

ON 27th January, 1928, Seethaiya, a Hindu male, 12 years, was admitted complaining of reeling sensation and falling. He was brought from the out-patient department on a stretcher.

Examination.—Abrasions 2 inches by $\frac{1}{2}$ inch on frontal and left parietal eminences. Scars due to falling, around both knees, lower half of right shin and middle third of left shin. Has a vacant stare and laughs inordinately. General intelligence that of a child of 8 years. Not dirty. Spare build. Incisors good. Skin and eyebrows normal, circumference of head $19\frac{3}{4}$ inches. Left ear to occiput $4\frac{1}{2}$ inches, right ear to occiput $3\frac{3}{4}$ inches. Both ears to sinciput $5\frac{3}{4}$ inches. Palate normal. Does not get up or change from side to side in the bed. Was bodily lifted from the bed and put on his feet thrice on the day of admission and twice on the 2nd day and he fell on all five occasions. No sensory or motor disturbances; other systems and temperature normal. Skiagram of the head did not show anything abnormal.

History.—No history or manifestations of syphilis. A somnambulist from the age of 7. From the age of 9 has been stealing food from other houses when he could. Reeling from the age of 11. During the last three months has been unable to walk, falling on his face or sides if he be put on his feet.

After the fall of the second day he was told about the good effects of hospital treatment, was persuaded to walk and promised lozenges if he did so. After that he was again put on his feet and slowly walked, later ran, and was discharged alright on 6th February, 1928.

AN UNDESCENDED TESTICLE IN AN UNUSUAL POSITION.

By FRANCIS CHRISTIAN, M.R.C.S., L.R.C.P., L.M.

WHEN I was going through my case book the other day I came across an interesting case which I believe will be worth recording. On the 21st July, 1924, I had an emergency call in the middle of the night and on going to the hospital found on the table in the waiting room near the operation theatre a boy about 14 years old badly gored by a buffalo, some 18 hours before his arrival at the hospital, with about 16 feet of the small intestine outside the abdominal cavity tugged together and tied up with dirty rags. His face and general appearance showed that the boy was suffering from great shock. I at once adopted the necessary means to counteract it.

Fortunately for the boy the protruded viscera had suffered comparatively little damage and I had only to resect about 4 inches of the gut and do an end-to-end anastomosis, the rest of the gut being uninjured and viable, though it had been roughly handled by his friends who brought him to the hospital and was covered with dirty materials for many hours. After thoroughly cleansing the exposed gut and the wound on the abdomen the former was replaced into the abdominal cavity and before closing up the wound on the anterior abdominal wall I had a final look in to see if everything was all right.

Now comes the important finding, and it is for the sole purpose of bringing that out that I have described this case here. At the level of the right internal abdominal ring, hanging backwards towards the posterior wall of the abdomen, was a small ball or sac attached by a thin, short pedicle and about the size of a healthy well-developed testicle. I was a little puzzled at first as to the nature of the tumour but on asking my assistant to find out if both testicles were in the scrotum the right one was found missing. Without this clue I believe I could not have made out by feeling alone what it really was as, unlike a testicle, this lump was more globular, softer and the epididymitis could hardly be distinguished and of course the testicular sensation could not be tested, the patient being under the anæsthetic. Inside the pedicle—if such a term can be applied to it—which was about half an inch long was a hard cordlike structure representing probably the vas deferens. In the erect position of the body this tumour must be hanging downwards in contact with the anterior abdominal wall. From the position of it I fear it will always remain a potential danger to the individual as it may be the means of causing strangulation or any one of the other possible accidents. To remove it at that time, I thought, was adding to the risk that the patient was already running.

The boy made an uninterrupted recovery and he left the hospital exactly on the 14th day after his admission. Before he left I made an examination of his right inguinal region and found that no defect could be made out by the mere examination of the part without taking into consideration the missing testicle from the right side of the scrotum.

OCCURRENCE OF CHYLURIA AFTER CONFINEMENT.

By S. SUNDAR RAO,

Darbhanga Scholar; Calcutta School of Tropical Medicine.

MANY years ago, Manson (1899) wrote that chyluria in women may often start soon after confinement, while in men any sudden physical exertion like running or jumping may precipitate an attack of chyluria. Since that

time, very little has been published on the factors that bring about such attacks.

The literature on chyluria in India is very meagre. The present instance is here recorded in order to draw attention to the necessity of a detailed study of all available cases both with regard to their clinical and laboratory findings and the factors which bring about these attacks.

Mrs. C., aged 22, had her first confinement at the Eden Hospital, Calcutta, without any complication in May, 1928. Twelve days after delivery she suddenly developed hæmato-chyluria and through the kindness of Lt.-Col. V. B. Green-Armytage, I.M.S., Professor of Obstetrics and Gynæcology to the Medical College and Surgeon to the Eden Hospital, who drew our attention to the case, she was admitted into the Carmichael Hospital for Tropical Diseases for observation and treatment. The following shows the results of the laboratory tests carried out:—

Blood for microfilariæ: Present, 25 per 20 c.mm.

Blood hæmoglobin: 80 per cent.

Total R.B.C. count: 3,800,000 per c.mm.

Total W.B.C. count: 9,000 per c.mm.

Differential count:—

Polymorphs	..	66	per	cent.
Lymphocytes	..	15	"	"
Mononuclears	..	8	"	"
Eosinophiles	..	11	"	"
<hr/>				
100				

Stool for protozoa: *E. nana* cysts present.

Stool for ova: *Ascaris* ova present.

Stool for bacteria: No non-lactose fermenters present.

Urine:—

Sp. gravity	..	1010
Reaction	..	Acid
Albumen	..	++++
Urobilin	..	Nil
Sugar	..	Nil
Indican	..	Nil

Microscopic examination:—

R. B. C.	..	++++
Microfilariæ	..	++

Temperature was normal. There was no abnormality in the circulatory or respiratory systems. Spleen and liver not enlarged. There was no family history of any importance.

The patient did not show any filarial manifestations excepting the chyluria and the heavy incidence of microfilariæ in her blood and in the urine. She was put on calcium lactate grs. xx t.d.s. and stock mixed vaccine of streptococci and staphylococci alb. and aur. (Filarial) twice a week. The chyluria cleared after four days. The attack lasted for a period of twelve days. Since her

discharge from the hospital to the time of writing, the patient has not had any relapse.

When the chyluria cleared, the urine which till then showed a large number of filarial embryos, did not show any embryos subsequently. But the blood which had a heavy incidence of microfilariæ, did not show any reduction in the number and has since continued in the same manner up to the time of writing.

The patient has a previous history of filarial infection. She was born in Rangoon and since her fifth year has been living in Bowbazaar, Calcutta, both of which places are endemic for filariasis. In 1924, she had an attack of fever with shivering, combined with an enlargement of the left inguinal gland. As the gland supplicated, it had to be incised. She had no further attacks of fever, nor any sign of filarial infection until the attack of chyluria twelve days after her confinement.

The other points of interest in the case discussed are:

The total absence of any filarial embryos in the breast milk of the patient as also in the blood of the baby, while the patient showed a heavy incidence of microfilariæ in her blood. As many as 25 to 60 embryos were present in 20 c.mm. of blood of the mother, while the three different examinations of the blood of the baby at night were entirely negative. The differential count of the baby's blood was as follows:—

Polymorphs	..	13	per	cent.
Lymphocytes	..	81	"	"
Mononuclears	..	—	"	"
Eosinophiles	..	6	"	"
<hr/>				
100				

The latter observation of the absence of filarial embryos in the blood of the newly-born infant, although possibly the first record from India, has been made from Fiji by Bahr (1910) who found "that the blood of newly-born infants of two filariated mothers gave negative results."

To summarise, the points of interest in the article are as follows:—

1. The onset of chyluria following confinement due to relaxation of pressure as also to the strain during confinement, either of which would cause the dilatation of lymphatics and their rupture.

2. The total absence of microfilariæ in the blood of the new-born baby and also in the breast milk of the mother even though the mother showed a heavy incidence of microfilariæ.

A CASE OF SYPHILITIC BASAL MENINGITIS.

By M. N. PAI,

LIEUTENANT, I.M.S. (T.C.),

Indian Military Hospital, Poona.

WATER CARRIER, aged 22, who was undergoing anti-syphilitic treatment, was admitted into the Indian Military Hospital, Poona, on 11th March, 1928, for chronic inflammation of the anterior cervical lymphatic glands on both sides of the neck. These were removed by operation on 13th March, 1928, and found to be tuberculous in nature.

From 9th April, 1928, the patient began complaining of headache and fever, the latter usually rose to 100° or 101° in the evenings. A few days later (14th April, 1928), the patient developed paresis of the facial muscles on the left side, his headache became more pronounced and his evening temperature continued as before. On 27th April, 1928, he developed ptosis of both eyelids and convergent squint with definite facial paralysis on the left side.

On 28th April, 1928, his condition was as follows:—

He had a vacant stare, convergent squint, ptosis, paralysis of the facial muscles on the left side and lay curled up in bed with his head retracted and the neck muscles slightly rigid. He complained of severe headache and his right hand and fingers were playing over his right temple. There was paresis of both legs, definite paralysis of the external rectus as well as paralysis of the orbicularis. His optic discs were normal and there was no papilloedema or signs of optic neuritis. All reflexes were present, ankle clonus and Kernig's sign were absent. The patient was dangerously ill.

The patient was given potassium iodide gr. 20 t.d.s. by mouth, 40 c.g. of sulfarsenol were given hypodermically and leeches were applied to the right temple. On 29th April, 1928, the dose was increased to gr. 30 t.d.s. and on 30th April, 1928, to gr. 40 t.d.s. On the evening of 30th April, 1928, his headache subsided and the temperature came to normal.

The dose was maintained at gr. 40 t.d.s. for three days and then reduced to gr. 20 t.d.s. On 2nd May, 1928, the squint completely disappeared, retraction of the head was absent and the patient was able to sit up in bed without any support.

By the 15th of May the facial paralysis had completely disappeared, his temperature had remained normal since 30th April, 1928, and the patient was discharged to duty on 16th May, 1928. He humorously attributed the cure to the leeches, which he stated "pulled out the bugs from his brain."

His blood culture was sterile, cerebrospinal fluid contained endothelial cells with only a few lymphocytes and gave a strongly positive Wassermann reaction.

Major H. B. F. Dixon, M.C., R.A.M.C., Specialist in Medicine, Southern Command saw the patient in consultation with me and afforded me great assistance by suggesting the rapid increase in the dosage of potassium iodide.

A CASE OF CEPHALIC TETANUS.

By HARENDRA NATH BAGCHI, M.B. (Cal.),

Resident Medical Officer, Police Hospital, Calcutta.

THE following is a case of cephalic tetanus (Kaf. tetanus of Rose) originating without any visible wound, characterised by stiffness of neck, trunk and limb muscles, without involvement of the jaw or any paralysis of the facial muscles. There was difficulty in swallowing and regurgitation through the nostrils on account of spasms affecting the muscles of deglutition, simulating hydrophobia. The case was afebrile throughout. Major B. G. Mallya, F.R.C.S.E., I.M.S., Police Surgeon, Calcutta, successfully treated this case and by his kind permission I am publishing this note.

Sukdeo Singh, a well-built constable, aged 28, came to hospital on 26th June, 1928.

History.—Headache and pain all over the body on account of frequent tonic spasms affecting in particular muscles of deglutition, trunk and limb muscles. If he tried to drink anything he used to be suffocated by it and some portion used to be regurgitated through the nostrils. Walking or standing were alike impossible owing to tonic spasm affecting his trunk muscles. He was in agonizing pain when these spasms came on, could utter no word and was bathed in profuse sweat after it. There was stiffness of his neck muscles from the beginning. No history of dog-bite, diphtheria, fits of any kind or of venereal diseases could be elicited. No visible injury could be found.

Examination:—

Gums.—Healthy. *Tongue.*—Clean. *Spleen and liver.*—Normal. *Bowels.*—Constipated for 2 days.

Heart.—Tachycardia present, otherwise normal.

Pulse.—96 per min. *Blood pressure.*—120 m.m. of Hg. (Systolic). *Mouth, tonsils, etc.*—Normal. *Lungs.*—Normal. *Reflexes.*—Normal. *Pupils.*—Equal and react to light. No discharge from his ears.

Onset.—Gradual. At first spasms were few and far between. There was only slight stiffness in the neck muscles and difficulty in swallowing liquids. Gradually the process extended and there was stiffness and spasm involving muscles of the body and

limbs (orthotonus). The day after admission there was discharge from his ears.

Treatment.—

26th July. Patient put in a dark cool room. Calomel gr. iii on admission followed by magn. sulph. $\frac{5}{16}$ i.

27th July. No motion. Soap and water enema: 2 ounces given without result.

Oil crotonis—min. i, on butter resulted in 5 clear and loose motions.

The following mixture was prescribed to be taken every 6 hours.

Re:

Chloral hydras	..	} aá gr. xv.
Ammon. brom.	..	
Pot. brom.	..	
Tinct. hyoscyamus	min. xv.	
Syrup auranti	.. $\frac{5}{16}$ i.	
Aqua $\frac{5}{16}$ i.	

Antitetanic serum 4,500 units injected daily for 4 days. Subcutaneous injections of (i) 2 per cent. sol. of acid carbolic min. 10 daily for 10 days, and (ii) 25 per cent. sol. of magn. sulph. 5 c.c. daily for 5 days.

Magn. sulph. $\frac{5}{16}$ i given on alternate days to keep bowels acting. Ear syringed and spt. acid carbolic dropped into ear, B.D. *Dict.*—milk diet with fruit juices.

Daily progress.—28th May. Sleep disturbed. Spasms at frequent intervals but lasting a shorter time than before. Can swallow with difficulty.

30th June. Disturbed sleep. Interval between spasms increased. Can drink better. Discharge from ears stopped.

2nd July. No sleep. Spasms at longer intervals and lasting a short while.

4th July. Spasms less than before. Slept well. Can take nourishment.

6th July. There were no spasms. Patient can walk with assistance.

Taking solid food now.

ALASTRIM OR SMALL-POX?

By S. C. NAG,

In-Charge, Barbheel Tea Estate Hospital, Tejpur, Assam.

As, almost in every epidemic, there is noticed a good deal of similarity, as well as some points of difference between alastrim and small-pox, physicians are always interested in these two diseases, the source of interest arising from the relationship which alastrim may or may not have with small-pox.

Below is given a short note on a small epidemic of what I provisionally call alastrim:—

Between February 20th, 1928 and March 20th, 1928, there were 21 cases of an infectious eruptive disease among the labour force of a tea estate. The ages of these patients

varied between 1 and 46 years, and all of them, except one, were previously vaccinated (eight being vaccinated only 1 to 7 years before). The disease was limited to the members of 7 families closely located in one line.

Regarding symptoms, primary fever was noticed in a few cases and it was of a mild type. In most of the cases the rash was small and scanty, but in a few cases the eruptions were large and profuse. In no case was the eruption so shotty. Vesiculation was not perfect in every case. Pustulation was not attended with rise of temperature, nor was the pustulation noticed in all the pocks. Umbilication was imperfect and occurred in not more than half the eruptions. Pitting was very slight and filled in in a few days, and under some eruptions there was no pitting. Crusts were not very hard and fell out in a few days. The eruption appeared all over the body—in some cases it was profuse on the face, in others profusion was noticed on the arm, in a few cases the eruption was noticed on the trunk and in one or two cases eruption was scanty in all parts. There were no complications and no deaths.

The patients and the contacts were isolated, and in the way of treatment weak carbolic oil with a trace of oil of eucalyptus was given to apply over the body. Iodine or potassium permanganate was not used.

Now the question may arise whether the above disease was small-pox, modified by previous vaccination, or whether it was alastrim—a different disease. It is, however, the combination of the following 5 points that tempts me to call the disease alastrim and to believe that alastrim and small-pox are two different diseases.

(1) Although all, except one, of the above cases were previously vaccinated, I revaccinated all the patients when they were ill, and in spite of their suffering, the vaccination was successful to some extent in those whose primary vaccination was performed long ago.

(2) The eruption was profuse in some of those who were primarily vaccinated 1 to 5 years before.

(3) The contacts i.e. the patients' relatives and attendants, who were secondarily vaccinated while in isolation, got the disease notwithstanding this recent vaccination.

(4) Constitutional symptoms were very mild and were noticed only in about half the cases.

(5) In some cases the constitutional symptoms were very mild, in spite of profusion of rash; had these cases been small-pox they would have shown severe constitutional symptoms.

(The writer does not seem to have considered the possibility of the disease being chicken-pox. Ed., J. M. G.)

FEBRUARY.

THE PROBLEM OF POPULATION.

Two recent publications deal with the health, or rather with the lack of health, of Madras City; one is a report issued in 1927 by a committee which was appointed by the Government of Madras to investigate the causes of the high mortality of the city and suggest a remedy; the other is the 1927 report of the health officer of the city. Both of these documents are of a most depressing nature, although in each of them a brave effort is made to maintain a note of optimism.

The death rate of Madras City for 1927 was 42.3 per mille; it is only exceeded in India by one other city, Nagpur, which has a death rate of 47.15. The birth rate of Madras is 46.8; that of Nagpur is 61.23. These rates are not accurate, but errors in registration are those of omission and, therefore, the true birth rates and death rates are probably higher than those which are recorded. It is interesting to note that if we deal with the large cities of India there is a general correspondence between the birth rates and the death rates, and the same thing holds true when we consider the cities of the world; for example, Cairo with a birth rate of 53 has a death rate of 33.3. England with a birth rate of 16.6 has a death rate of 12.3 whereas in 1871-1880 the figures were 35.4 and 21.4, respectively. So that the birth rate and the death rate have fallen steadily and rapidly in sympathy with each other.

Madras City is divided into thirty divisions; if we take the fifteen divisions which have the highest birth rates we find that no less than twelve of these are among the 15 which have the highest death rates.

Comparing the rates for the various communities of Madras the same thing holds true, the birth rates are highest among the Moslems with 53 per mille, next in order being the Hindus with 47.2. Anglo-Indians (42.8), Indian Christians (37.8) and, last of all, the Europeans (19.0). The death rates are in exactly the same order being 49.3 per mille in Moslems, 42.9 in Hindus, 31.9 in Anglo-Indians, 30.7 for Indian Christians and 7.8 in Europeans. Statisticians have revelled in constructing curves of birth rates, death rates and population; they have shown that in settled communities, when there are no catastrophic occurrences, the population curve tends to reach a steady maximum which can only be exceeded if some new factor is introduced.

The average man is very sceptical where statistics and curves are concerned, but in the case of these birth rates and death rates the evidence is so overwhelming that the curves merely represent a graphic method of displaying obvious facts. Some statisticians ask us to believe that there is some mysterious and almost supernatural process at work which brings about the balance of population, but though we may admit that the factors concerned are complicated and variable it is not difficult to see how the limit of population is reached in the case of communities like those of Madras City. In each city the total available income of the population is strictly limited, it consists of (1) salaries derived from Government and other official appointments, (2) the wages, salaries and profits of people engaged in industries, (3) trading profits, (4) incomes derived from property outside the city, and (5) other miscellaneous sources of income. The only item which is capable of great expansion is (2) and even this is limited by conditions which are not easily controlled by governments or other organized agencies. The total income of the city is all that is available for providing food, clothing, houses, roads, water supplies, drains, etc. for the whole community, and so far as can be seen, the amount in the case of Madras, is only sufficient to maintain the existing population on a low economic level, many of the people being almost on the verge of starvation. Assuming that there is neither emigration nor immigration it is obvious that so long as the people of the working and clerical classes continue to marry and bring numbers of children into the world while the parents themselves are undeveloped and are unable to maintain themselves in comfort, the population as a whole is bound to suffer from serious under-nutrition with the inevitable result of a high infant and adult mortality. In the case of Madras a high birth rate must inevitably be followed sooner or later by a high death rate unless some fresh sources of income can be tapped or emigration restores the balance between food and population. Take what happens in the case of a typical family under existing conditions. An immature youth, before he is able to maintain himself in reasonable comfort, marries a wife who is equally immature; she proceeds to have infants for whom sufficient nourishment is not available, the whole family suffers from malnutrition, half of the children die before they reach the age of five and the survivors are stunted and inefficient. Multiply this example thousands of times and you have a picture of what is happening in Madras as well as in many other places in India. It is surely sufficiently obvious that so long as the people insist on having such high birth rates they must continue to submit to the toll which is levied by disease and malnutrition.

There are two obvious remedies, which must be applied together; one of these without the other will be useless.

The first remedy is the prevention of the disabling diseases which seriously lower the efficiency of the people, and the second the adoption of a system of later marriages and the exercise of self-control or some other kind of control in connection with reproduction.

Hitherto we have been preaching disease prevention as the one panacea for the ills of India and we have been pointing to the triumphs of medicine in European countries; but we have ignored the fact that hand in hand with disease prevention other factors have been at work in Europe: smaller families have been coming into fashion, the development of industries has been raising the economic standards of the people to a much higher level and a tide of emigration has been relieving the stress of population. Had the people of Europe followed the Indian custom of early marriage and unrestrained propagation, the state of affairs there would probably be no better than in India to-day. In Ireland in the last century there was a striking example of what happens to people who indulge in unrestricted multiplication; the population in 1840 was over eight millions or more than twice what it is to-day and the people were living in conditions which would horrify the average Indian peasant. Then came the potato famine which demonstrated in a terribly ruthless manner the unsoundness of the economic position; it was only when the population was reduced to four millions by death and emigration that a new era of prosperity was introduced.

In India there are no longer catastrophes such as kept the population down in former times; the people suffer instead from a long-drawn-out misery to which they have become so accustomed that it is regarded as a dispensation of God, whereas it is really the inevitable consequence of ignorance and stupidity. What is needed is that the best brains among the economists, sociologists, agriculturists, industrialists, educationalists and medical scientists should be set to study the problem and to indicate clearly what we ought to teach the rising generation. At present we instruct them in the useful accomplishments of reading, writing and arithmetic, but we leave them to grope blindly in the dark in the matter of adapting themselves to their environment and of learning how to live healthy lives. The problem is difficult and complex, but we have no right to say that it is insoluble until we have made a serious effort to solve it and the sooner a beginning is made the better.

CORRIGENDUM.

January number 1929, page 50—*Tropical Gynaecology* by Lt.-Col. V. B. Green-Armytage: for "Pp. xv plus 842 with 3 plates and over 100 photographic and other illustrations. Price Rs. 20" read "Pp. ix plus 249, Price Rs. 3-8."

SPECIAL ARTICLES.

THE CAMPAIGN AGAINST LEPROSY.

By E. MUIR, M.D., F.R.C.S. (Edin.),

Research Worker in Leprosy, at the School of Tropical Medicine and Hygiene, under the Indian Research Fund Association.

SINCE the inception of the Indian Council of the British Empire Leprosy Relief Association in 1925, a considerable amount of new interest has been taken in leprosy. The old method of forcible segregation has been replaced by voluntary clinics, training of doctors, investigation into local causes of high endemicity and propaganda based upon such investigation.

Although we do not as yet possess any cure for leprosy which may be called "a specific," yet we have at our disposal treatment which, when properly administered, will in the great majority of early cases, rid the patient of all active signs and keep him well, provided he continues to take the proper precautions; it will also heal up a large proportion of more advanced cases.

This fact has changed the whole aspect of the leprosy problem:—

(1) Leprosy now comes within the range of the physician instead of being looked upon as an infirmity and classified along with deaf-mutism and blindness as permanent and incurable.

(2) Patients formerly hid their disease as long as possible, fearing loss of employment and social ostracism, till it reached an advanced and comparatively irremediable stage. Now they come forward for early treatment in the hope of having the disease arrested before it becomes infectious or difficult to treat.

(3) Doctors who had little opportunity of studying leprosy in their college days, now have an opportunity for special training. Leprosy is a difficult disease to understand and has many aspects which differ from other diseases; therefore reading the literature is not always sufficient, and training by an expert is advisable.

(4) It is recognised that leprosy is more highly endemic in certain places and among certain classes of the community than in others. With a view to prevention it is very important that the causes of the disproportion should be investigated.

(5) Leprosy is an easily preventible disease. The spread of the contagion is dependent on ignorance, superstition and certain bad customs. If doctors have had little opportunity of knowing about leprosy, the people at large have had still less. Propaganda, therefore, is necessary among the people in general but especially within endemic districts and villages.

(6) As most of those afflicted with leprosy in the villages are poor and unable to afford to pay much for treatment, as the village doctors have not yet been thoroughly trained to treat leprosy, and as most doctors through ignorance are afraid to touch or come near leprosy patients and are therefore unwilling to treat them, it is necessary to start leprosy clinics in village centres in endemic areas so as to place treatment within the reach of all.

The above will be sufficient to show the new lines along which leprosy may be dealt with. I think that merely stating the case is of itself sufficient to show that more hopeful results are to be expected by dealing with leprosy in this way than by merely segregating conspicuous pauper lepers, the great majority of whom have already passed through the infective stage, when they were really a danger to others, and have reached the comparatively harmless end-stage of deformity and disability which drives them to beggary.

During the last two years the British Empire Leprosy Relief Association has taken definite action along these lines. A survey party has made sample surveys in Bihar, Bengal, Burmah, the Central Provinces and Bombay. Not only have interesting and important facts been elicited as the result of their investigations, but the interest raised has resulted in the formation of clinics and a continuation of the survey along the same lines by trained doctors appointed by the provincial authorities.

The lines along which propaganda-treatment-survey work is run and the interest aroused are well illustrated by extracts from a report by Dr. I. Santra on work in the Akot taluk of the Akola district of Berar.

"Police station Akot is the northernmost part of district Akola. Its northern part is hilly and sparsely populated, while the southern part has a rich soil and is well populated.

Statistics:—

Area—206 sq. miles.

Population—42,878.

No. of villages surveyed:—

On the plains—71.

In the hills—19.

Total—90.

Lepers per sq. mile—2 (approx.)

Lepers per 100,000 population—949.

Percentage of villages affected:—

On the plains—44, or 62 per cent.

In the hills—7, or 36.8 per cent.

Leprosy census.—The number of lepers for Akola district according to the census of 1921 is 542. The Deputy Commissioner's census for the district is 2,153, or 4 times the census figure. The D.C.'s figure for police station Akot is 150. Our figure for Akot is 407. We have seen that the D.C.'s figure for Akot is 4 times the census figure; if this be relatively true for the area of thana Akot, then our figure for Akot is about 10 times the census figure of 1921.

One remarkable fact during the village survey was that lepers came voluntarily to be examined. The disease is well recognised by the villagers and since there is no social ostracism for a leper, he comes voluntarily to be examined. In a certain village a man came to one of our workers and said 'Doctor, I have got leprosy.' No signs of leprosy being visible the doctor said: 'You are not a leper.' The man retorted 'What do

you say? Here I pull out my hairs, and I don't feel,' and he began to pull out hairs from his leg.

It seems that there is an idea in the Central Provinces that there is more leprosy in Chattisgarh than anywhere else. We found more leprosy here in Akot than anywhere else. The reason why Chattisgarh has come into prominence is that the many leper asylums working in Chattisgarh have been trying to enlighten the public and the government about the existing state of leprosy there, while in Berar the people having enough to eat do not need to go begging and thus the lepers have not created conditions calling for the establishment of many leper asylums nor have they attracted the notice of the authorities.

Cases surveyed belong to the following classes:—

A1	175
A2	65
B1	68
B2	63
B3	36
Total	407

The number of A1 cases is proportionately more than in other places which may mean, either that we have failed to get all the A1 cases in other places while we have seen all the A1 cases here, or that the disease has been recently increasing, giving rise to so many new cases. The period during which these A1 cases have originated is synchronous with the increased communications due to the recently introduced motor traffic. We have enquired in the villages regarding the increase of the disease. Many said it had been present all along in their villages. Some said that now they have been seeing more cases. We leave it to the leprosy expert of the province to determine this point.

Leprosy on the plains and in the hills.—The reason why the percentage of affection of the villages in the hills is nearly half that on the plains is not that the hill peoples are healthier or take better food than the peoples of the plains, but is due to the sparseness of the population and absence of intercommunication. The people living on the borders of the Male Ghat Hills are the Korkus, Bhils and Nehals. We went as far as Koha, 36 miles from Akot and in the midst of the Male Ghat Hills, to enquire whether the hill people have leprosy among them in their own homes. It seemed to us that once upon a time these people were healthy and strong taking an active part in the communications between northern and southern India; but now as they live in the reserve forests their land is very limited, they do not kill animals for food, and as a result they looked to us very degenerate. Their love for animal food is so great that if they see vultures circling round an area the whole village follows them and gets at the carcass of the animal (probably dead of disease or old age) and brings it with great joy. They make their living by repairing roads and working for the forest department while they come down to the plains in the season as labourers. They have no indigenous name for leprosy. They call it 'Korhya' derived from the Urdu word 'Korh.' 'Korh' is a word that is in use in the parts north of the Male Ghats; 'Raktapith' and 'Maharoge' are words used in the south. The hill people probably had no leprosy amongst them and hence they have no indigenous name for it. When the northerners made their way to the south through these hills they must have taken the help of the Korkus. So the Korkus, having first come in contact with the northerners, might have seen leprosy amongst them or the northerners might have found leprosy amongst the Korkus and hence the origin of the word 'Korkya' (meaning the man who is a leper). We asked old men of the villages about the origin of the disease. They said they had seen it from their boyhood and they began to name lepers living far and wide in the hills. A B3 case in a village bordering the hills gave a history that 6 years before he got the disease two of his leper relatives, probably B cases, came down to the plains to work and used to stop at his house at night.

The different castes are affected in the following numbers:—

Kunbi	.. 88	Mahratta	.. 15
Mahar	.. 63	Chamar	.. 12
Mali	.. 51	Gond	.. 8
Musalman	.. 27	Rajput	.. 6
Bari (Growers and Sellers of Betel leaves)	.. 17	Mahali	.. 5
		Others	.. 115
TOTAL			.. 407

The four most affected castes have 229 lepers.

The other 33 castes have 178.

The Kunbis are similar to the Kurmis of the Hindi-speaking country. Kunbis and Malis are cultivators. The well-to-do Kunbi represents himself as a Mahratta. Some say that the Kunbis are a part of the Mahratta nation. As for Mahars, Dheds and Mangs, though they occupy a position of considerable social degradation, few villages can exist without their services. They remove the dead animals, assist at funerals, help in the government work of collecting revenue, run errands, keep the public peace and work in the spinning and weaving mills."

Another method of combating leprosy has been adopted by the Bengal Branch of the British Empire Leprosy Relief Association. The amount of money available was small, only about Rs. 4,500 a year. It was decided to appoint a doctor as a propaganda officer and send him to the different districts of Bengal to spend a month in each and while there to train doctors, initiate dispensaries and make as far as possible a general survey of the prevalence of leprosy in the district. The following report for the month of November 1928 which was spent by the propaganda officer, Dr. Ghosh, in the district of Dacca shows the value of this method of working.

"As arranged, I arrived at Dacca on the 1st November, 1928, in connection with leprosy propaganda work under the auspices of the Bengal Branch of the British Empire Leprosy Relief Association. I had to deliver a series of lectures to the doctors in different batches and to the senior students of the three medical institutions. I saw the Civil Surgeon and Capt. P. Ganguly of the Medical School on the 2nd November, 1928, and arranged my first course of lectures to the teachers and demonstrators of the Dacca Medical School and to the senior students of the Dacca Medical School lasting for 4 days from the 5th November to 8th November, 1928, both days inclusive.

2nd Course. Place—Jaggannath Intermediate College. From 12th November, 1928 to 15th November, 1928.

This lecture was kindly organised by Capt. Ganguly and Dr. P. C. Sen, the Health Officer of the Municipality, for the private practitioners of Dacca town. Altogether 19 doctors attended the course and took a great interest in the subject. I got several cases for demonstration to the doctors.

3rd Course. Place—Dacca Medical School. From 19th November, 1928 to 22nd November, 1928.

This was organised by the Chairman of the District Board for the benefit of the District Board doctors only. Altogether 29 doctors attended this course. At first I suggested to the Chairman of the District Board that I was ready to take the D. B. doctors in 2 batches, but it was the intention of the Chairman that if the doctors attend in one batch they can have a discussion with me after the course of lectures as to the future running of a leprosy clinic. This was a good idea. The Chairman of the District Board is very sympathetic and is taking a good deal of interest in the leprosy problem of the district. He is also the Vice-Chairman of the Municipality and I hope he will try his best to start some

centres as early as possible. The Health Officer of the District Board is also very keen. He himself attended one of the courses.

4th Course. Place—National Medical College. From 26th and 27th November, 1928.

This short course was meant for the senior students of the National Medical College. About 250 students attended the course together with some of their teachers.

5th Course. Place—National Medical College. From 26th November, 1928 to 28th November, 1928.

I had to deliver the last of my series of lectures to the teachers and senior students of the National Medical Institute. Twenty doctors and about 250 students of the Institute attended the course. The Superintendent of the Institute and Dr. Bose, are to be thanked for the excellent arrangements made for the lecture.

Leprosy Film.—First time shown on 19th November, 1928, at the Empire Theatre, for the Commissioners of the Dacca Municipality and the general public. This was organised by Dr. Sen, Health Officer of the Dacca Municipality. The hall was packed to suffocation, all available seats being filled up.

Second time shown on the 21st November, 1928, at the Cinema House, specially meant for the doctors, students and nursing staff of the Dacca Medical School. About 600 persons attended.

Third time shown on 23rd November, 1928, at the Cinema House. This was organised by Capt. Ganguly. The attendance was quite good. About 250 ladies were present on that day.

Fourth time shown on 27th November, 1928, at the Empire Theatre, for the students of the National Medical College and the National Medical Institute. Altogether 500 persons attended.

In this connection I must thank the proprietors and Directors of the several Cinema companies of Dacca for placing their halls, their operators and projectors at our disposal free of any charge. It would not have been possible to arrange for so many shows if we had had to pay for these shows.

Leprosy Survey in the Dacca District.—As it was not possible to begin the actual survey of any thana I wrote to the District Health Officer asking for immediate information about the incidence of the disease in the various parts of the district. This will help us in selecting suitable places for starting leprosy clinics in the rural areas. When I left Dacca I did not get all the information that I had wanted from the Health Officer. I hope to get the required figures within a week's time. According to the 1921 Census there are 675 lepers in the district. I had to remain content with only a partial and rough survey of the Dacca Municipal area. One day I went out with the Health Officer of the Municipality and was able to detect nearly 15 advanced cases amongst the sweepers of the municipality. Another day I visited the densest part of the municipality and got as many as 15 cases in one lane. (Shakharibazar Street). All those cases were among the conch-shell manufacturers. They are doing all sorts of work, mixing with the public and taking no care of themselves though they know that they are lepers. They generally live in overcrowded, dark and insanitary houses. I wanted to take a photo of one of the houses in which they live but could not do so for want of a camera. I visited some other localities and was able to get cases everywhere. In all I saw about 65 advanced cases (B3 & A2) and a few early cases. If a systematic survey be carried out I think that there will be not less than 300 cases in Dacca town alone.

Capt. Ganguly and Dr. Sen, the Health Officer of the Dacca Municipality, are also of the same opinion.

Treatment Centres.—There is an outdoor leprosy clinic attached to the infectious ward of the Mitford Hospital under the direct supervision of Capt. Ganguly, but the attendance was not very satisfactory only 5 or 6 patients attending. But as a result of the propaganda work during the last month more patients are now attending. I opened another centre at Nilket for the benefit of the municipal sweepers and others. I hope

the authorities of the municipality will continue to treat the cases. In this connection I saw the Chairman of the municipality and discussed with him the possibilities of starting a leprosy centre at Dacca. He told me that as there was a leprosy clinic at the Medical School, Dacca, he did not see the necessity of starting another centre. However, after he had listened to me and the Health Officer he was convinced of the efficacy of such a treatment centre and promised to start a centre as early as possible.

I also saw the Chairman of the District Board and discussed with him about starting 4 centres in the rural areas. He was very sympathetic and I hope he will try his best to start some centres as early as possible. I suggested that one centre should be opened in each subdivision."

It is very important that, when doctors are trained in leprosy in any area, there should be a leprosy dispensary started in that same area under expert direction so that there may be a practical demonstration of the effects of treatment. This will lead patients and the public to realise that leprosy is remediable, and will act as a centre for propaganda.

One of the chief difficulties in getting patients to come for treatment and to continue treatment long enough is the belief that leprosy is irremediable. This prejudice can only be broken down by actual demonstration of results, and to do this in a new area there is required a well-conducted dispensary run by a doctor who has had considerable experience of leprosy treatment. This also gives confidence to other doctors to treat cases and provides a consultant whose advice they can seek in difficult cases.

HINTS ON THE VILLAGE NURSE SCHEME.

By G. McGUIRE, I.M.D.,

Civil Surgeon, Karnal, Punjab.

SEVERAL attempts have been made in the past to provide medical relief to India's millions and the Punjab has at last given the lead by providing rural dispensaries.

Not much attention so far, however, has been paid to the solution of the problem of medical aid to the women in the villages, who suffer torture, nay, death at the hands of the antediluvian, dirty, indigenous dai, rather than take advantage of the facilities offered in a rural dispensary in charge of a male doctor.

The horrors of confinement are seen everywhere, in a hovel in the poorest village and in the rich palaces. You will be told that carpenter's tools are used in cases of obstructed delivery.

It was in the middle of the year 1925 that an attempt was made, with the assistance of my wife and in the face of a great deal of ridicule, to provide some help for the women in the villages by adding to the number of qualified nurses in the district.

Local bodies could not be approached for aid as one could not expect that they would dole out money on an experiment, for a scheme in its initial stages.

Beset with difficulties, subscriptions were started, the obstacles were gradually overcome and eventually money poured in. The response was so satisfactory that the original plan of having 2 or 3 additional nurses was abandoned and a nurse at every dispensary in the district was the goal aimed at.

Enthusiasm being roused, the whole district at last was convinced of the utility of the scheme, and people came forward in numbers of their own accord asking for the services of trained nurses. The District Board, at this stage, were prevailed upon to pass a resolution providing

a nurse in every dispensary if subscriptions of Rs. 1,500 were raised by the people of the area.

This is how, from two nurses in the district there are now 22 working in the rural areas, breaking through the prejudices and superstitions and rendering help to the women in the villages at a time when it is most needed.

AIMS OF THE SCHEME.

The aims of this scheme are to supplement a much felt want in the rural areas, as it is not possible in the near or distant future to have a relay of trained lady doctors.

Nurses and nurse-daïs trained in midwifery would, therefore, be able to play an important part in reducing puerperal fever, ousting the untrained indigenous dai from her secret haunts and, in time they will be called upon to play an important part in the general and social uplift of the women.

This scheme once started, with a nurse or nurse-dai in every dispensary, will soon break the first barriers of superstition and prejudice.

Let there be a small beginning and employ the illiterate trained nurse-dai who can mix freely with the women of the villages. She will instil greater confidence and work will soon be established.

When this stage is reached, nurse-daïs of this class could be drafted out into the villages away from dispensaries to train and control the untrained indigenous daïs and supply them with the necessary equipment for normal labour cases. In their place the better and more educated type of women with a nurse's diploma could be posted. The mentality of the rural folk being now prepared, it would not be a difficult task for the nurse to launch out on instructional lines as well, in health, nursing, etc., and to contribute largely to the happiness of the women in the villages.

No dispensary should be without a nurse, and no village without a trained nurse-dai to supervise the work of her untrained sister, instruct her in cleanliness and supply the wants necessary for a successful confinement. If we are going to wait for knowledge to penetrate in its own good time from the larger towns and cities where so many facilities exist and so much is being done for the women, then we are going to wait for centuries and even then a large part of our work will remain unaccomplished in spite of the strenuous attempts at education.

Prejudices and superstitions in the villages can only be broken through the agency of medical aid which, in India, is held in high esteem and, therefore, the education of female rural children should go hand in hand with medical relief.

It is not intended that these nurses should take the place of lady doctors and even though these nurses would fail to be useful in obstructed delivery, thousands of women whose labour is normal and who nowadays die from puerperal fever through sheer neglect and want of ordinary aseptic precautions at the hands of the ignorant untrained indigenous dai, will be saved.

With a scheme of this nature we shall have a large body of women scattered throughout the length and breadth of the Punjab working silently for the general uplift of the rural women, and in a quarter of a century these women in turn will be moving forward towards the goal of modern civilisation.

HOW TO BRING THE SCHEME INTO EXISTENCE.

It is not intended that every civil surgeon in the Punjab should attempt to start on the lines on which the scheme was first started, as this means time, labour, money, and also a certain amount of good fortune. There are, however, three important methods by which one could start the scheme on a sound basis.

- (a) Government aid.
- (b) An independent body working under the orders of the Inspector-General, Civil Hospitals, Punjab.
- (c) A Ladies' Committee in each district with the wife of the Deputy Commissioner as President.

Given the money, and all other considerations being fulfilled, we have to look around for the material. It will naturally be asked where and how it is to be obtained.

The Ludhiana Medical School is the chief training centre at present and other Mission Hospitals also play a small part in training nurse-dais. Even if these institutions were given a grant to expand their activities and to provide teaching facilities, they would be unable to meet the requirements of the Punjab.

Scholarships of Rs. 30 p.m. to nurse candidates and Rs. 20 p.m. to nurse-dai candidates with free quarters would be a great inducement.

Deputy Commissioners, who exercise a great deal of influence in the districts, will find no difficulty in providing the candidates. Christian villages are to be found in every district and these folk have no prejudices and will be glad to take up the profession. There are poor Mohammadan women, also, who would be glad to earn a living. The Arya Samajists are also coming forward in the field of advancement, and they, too, would supply women and thus balance each community. Then there are also the indigenous dais who could be selected for training on the same condition.

A certain number of scholarships should be allotted to each district for candidates trained yearly at each district and tehsil head-quarter hospital.

Candidates are more likely to come forward for training in their own district than go elsewhere owing to family considerations, etc. Illiteracy should not be a disqualification at the onset for the nurse-dai certificate.

Four scholarships of Rs. 30 p.m. and four of Rs. 20 p.m. should be allotted to each district and half the number to tehsil head-quarter hospitals.

Candidates who know sufficient English to pass the 5th grade dispenser's examination should be given Rs. 30 p.m. and permitted to undergo a four years' training for the nurse's diploma. Those who can read and write the vernacular or are illiterate should be given Rs. 20 p.m. and a nurse-dai certificate would be granted to them after two years. Candidates willing to work in the male wards should be granted a higher scholarship.

The indigenous dai should be given the same scholarships as the nurse-dai if she consents to undergo her training at district or tehsil head-quarter hospitals. On completion of their training these nurses and nurse-dais should be sent to the central midwifery training ground (Ludhiana) for a period of three months to witness an additional number of maternity cases, to obtain a wider outlook, and to appear for their examination.

Those who are successful should be provided for by the local bodies. Assuming that sufficient material in midwifery is not available at district and tehsil head-quarter hospitals for the necessary training, it must not be forgotten that the training of nurses comprises other branches also. Their time could, therefore, be well spent in the study of cleanliness, first-aid, nursing, hygiene, etc., and their knowledge of midwifery could be supplemented by instruction on the dummy. Their last three months at Ludhiana would then fit them to administer help in normal labour to their sisters in the remotest villages.

The presence of these nurse-dais working out in the districts, would also help to secure a supply of material for the district and tehsil head-quarter hospitals. These women would eventually exercise a great deal of influence in the villages, and they could be instructed to send cases to these hospitals, thus supplying the necessary material for training purposes.

THE AMENABLE INDIGENOUS DAI.

I lay particular stress on the training of these persons as they form the pivot around which centre all things pertaining to women in the villages.

They should be induced as with their experience to take a training at any cost, 6 months on scientific methods, a course of training for excellent dais. A certain number would turn them into training and 1 month's graduate work yearly at the district or tehsil head-quarter hospitals, would be a

good beginning. The scholarship of Rs. 20 per month would be an encouragement for them to come forward.

Those who are not willing to leave their villages should be allowed to attend their rural dispensaries for a year with a scholarship of Rs. 10 p.m. and then induced to go to the head-quarter hospitals for 3 months to entitle them to their certificates. These persons could be employed in their own villages or in a village where a dispensary exists and given a lower rate of pay than the trained nurse-dai, viz., Rs. 25 to Rs. 35 p.m. They would then be under some control and with facilities at their disposal (free supply of lotions, dressings, etc.), they would play an important part in reducing puerperal fever. The indigenous dai is faced with two great evils at present. Ignorance of cleanliness, and the custom of receiving for the services she renders a sum which is hardly sufficient for her existence, much less to provide her unfortunate patients with the expensive necessities which medical science demands.

THE UNWILLING INDIGENOUS DAI.

Some are too old for any sort of training, while others are like volcanoes who pour out a volume of abuse on any innovation. A keen medical officer, and an equally keen nurse should win them over, pay them an honorarium of Rs. 5 p.m. or else pay them the fees they are ordinarily entitled to from each patient, and let the patient pay them also and in this way bind them down to send for the trained dai of the village for every confinement case. Give them full facilities and let them do the work under trained supervision and also attend to the soiled linen of the patient. One of them could be employed as a permanent assistant to the trained nurse and paid Rs. 10 p.m.

Sanads, in gold letters, which are highly esteemed by rural folk, should be given for help and assistance afforded to the trained nurse.

The medical officer should keep a register for the indigenous dais in his village, and when they report to the dispensary for their dues inquiries can be made from them of the work done independently and the number of deaths, the medical officer having previously obtained this information from the police.

When the indigenous dais report to the medical officer of the dispensary for their dues it will be a sort of pseudo-registration and will convey the impression of "non-absolute independence." Unless the country has sufficient numbers of trained dais, legislation cannot be enforced to prevent the untrained from working, but as soon as the supply equals the demand we could then take upon ourselves to prohibit the untrained from working in villages where dispensaries exist. In this way control will be established and new indigenous dais will be prevented from taking up the profession. Once work is set in motion, compensation and other rewards should be gradually reduced and the savings thus effected should go towards extending the scheme.

Do not condemn the indigenous dai, as it is poverty, force of circumstances and ignorance in cleanliness that places the high rate of mortality at her door.

DIFFICULTIES TO BE OVERCOME.

1. The first impression to be dispelled will be that a nurse-dai has not been posted for the purpose of reporting cases of infanticide to the police.

2. You will be told that custom has taught wives to believe that to change their dai for the trained nurse is like changing their husbands.

3. The trained nurse should not be allowed to take fees. It would be better to pay her compensation of Rs. 5 p.m. instead, otherwise she will not be able to stand in the field of competition with the indigenous dai, whose fees are As. 4 for a male and As. 2 for a female child, whether called during the day or night. For this small sum she is expected to pay regular visits for ten days, attend to the soiled linen of the mother and child and, if Fate decrees, knead the patient out of existence. If the trained nurse is allowed any fee at all it should compare favourably with that of the

indigenous dai but she should be provided with an assistant to wash the soiled linen.

4. False rumours circulated by the indigenous dai, hakims and vaidas will have to be overcome.

5. The greatest difficulties are the obstacles put in the way of the nurse-daids by medical officers who fear loss of prestige and practice. This can be overcome by the controlling authority in the office of the Inspector-General, Civil Hospitals. This controlling authority is very essential to ensure assistance from the medical officers and to promote enthusiasm for the furtherance of this work in the early stages.

6. Another great difficulty is the independence of the nurses and nurse-daids owing to the demand being greater than the supply. They have no fear of losing their appointments as they are readily provided for in another district, sometimes on a higher salary. These ideas have encouraged laziness in their duties, and frequent dismissals and resignations follow so that the work is retarded. If the output equals the demand and employment is debarred to those who have been dismissed, good work will soon be noticed.

8. Under no circumstances should medico-legal work, of any description, be allowed by nurses or nurse-daids. Infringement of this rule should be most severely dealt with.

LADIES' COMMITTEE.

This should comprise the wives of the officials and other ladies interested in the welfare of the women. If the wife of the Deputy Commissioner were to pay an occasional visit to some of the nurses and nurse-daids news would soon go round, and molestation of the nurses would be of rare occurrence. This would also instill confidence in the nurses. A lady doctor from headquarters touring the district sometimes and a few lady sub-assistant surgeons posted to rural dispensaries would also act a great stimulus.

FACILITIES TO BE GRANTED TO TRAINED NURSES.

1. A small monthly allowance of Rs. 5 p.m. should be paid and no private practice allowed.

2. For all maternity cases they should be authorised to supply free medicines, dressings and diet to poor patients, either at the hospital or at the patient's home.

3. A female assistant on Rs. 10 p.m. should be provided to serve as a protection, to wash the soiled linen and to do the other dirty work free of charge.

Indigenous daids who can live in the hospital premises and are willing to take up work as assistants should be given preference as an experimental measure.

The wives of sweepers of the dispensaries would be very useful also as assistants and no objection will be raised as a large number of this class carry on the work of indigenous daids.

4. Husbands of nurses should be provided with posts as school masters in the same village, or else given preference of employment in a rural dispensary or other appointments in the village.

5. Trained nurse-dispensers or nurse-daids, employed as a means of protection for the nurse posted to the dispensary, would double the expense and the difficulty of washing the soiled linen would still continue.

6. The class of female dispensers should be abolished. Every female employee (except menials) should have a midwifery qualification.

POST-GRADUATE WORK.

This should be insisted on for all classes of nurses.

1. *Nurses*.—They should be deputed for three months at a central training school (Ludhiana) every three years and given all inducements in pay, travelling allowances, etc.

2. *Nurse-daids*.—They should be deputed for the same period and at the same centre every two years.

3. *Indigenous Daids*.—They should undergo their training at the district or tehsil head-quarter hospitals for a month each year.

If efficiency is to be established post-graduate work is essential.

PAY TO THE NURSE AND NURSE-DAIDS.

- | | |
|--|--|
| 1. Nurses in male wards .. | Rs. 70 to Rs. 80 p.m. and free quarters. |
| 2. Nurses in female wards .. | Rs. 55 to Rs. 70 p.m. and free quarters. |
| 3. Nurse-daids for male wards who are able to read and write English. | Rs. 50 to Rs. 65 p.m. and free quarters. |
| 4. Nurse-daids for female wards who are able to read and write English. | Rs. 45 to Rs. 60 p.m. and free quarters. |
| 5. Nurse-daids for male wards who are either illiterate or can read and write only the vernacular. | Rs. 45 to Rs. 55 p.m. and free quarters. |
| 6. Nurse-daids for female wards who are either illiterate or can read and write only the vernacular. | Rs. 40 to Rs. 50 p.m. and free quarters. |
| 7. Trained indigenous daids .. | Rs. 25 to Rs. 35 p.m. and free quarters. |

Private practice should not be allowed in the villages. Rs. 5 p.m. as compensation should be paid.

WORK TO BE EXPECTED FROM NURSES AND NURSE-DAIDS DURING THE FIRST YEAR OF SERVICE.

A nurse or nurse-dai on first being appointed will find that she has very little to do for the first month beyond attending to the women and children of the out-patient department of the dispensary. She should, therefore, embark on her duties at once by doing house-to-house visiting daily and making it a part of her duties to become intimate with the indigenous daids of the village, wives of the school master and sub-inspector of police and other important residents. Before the month comes to a close, with a keen medical officer helping the nurse, an increase of the women and children attending the out-patient department will be the first signs of her popularity. In the first three months she should have two or three maternity cases to her credit and at the end of 6 months a monthly average of 3 cases. Her average work for the year should not be less than 6 cases monthly. If the monthly average for the first 3 years is 10 I would call this a good record.

Government, or the local bodies, should insist on 15 cases of confinement monthly from each nurse after the third year of service. No nurse or dai should be entitled to promotion if she does not attain to this standard. To work up to this degree of success she will have to keep up a high level of popularity and thus she will be in a position to undertake other useful work also.

A hall, with a purdah wall and a garden in a remote corner of those dispensaries with large compounds, would add to the already existing facilities for a happy village life. The building would serve as a meeting place for instructional purposes, where an exhibition of babies' requirements, first-aid equipment and other domestic necessities, would all tend to improve the knowledge of the women.

RECORD OF WORK OF NURSES AND NURSE-DAIDS IN THE KARNAL DISTRICT FROM 1ST JANUARY TO 30TH JUNE, 1928.

The record given below is very encouraging though it was carried out under most trying conditions. Nurses were obstructed in their duties. Several nurses resigned or were dispensed with thus throwing the work back. Confusion followed, often creating an impossible situation as it was not easy to replace the nurses.

Name of Dispensary.	Nurse or Nurse-dai employed.	NUMBER OF CONFINEMENTS.		Total confinements.	REMARKS
		In Hospital.	In the village.		
1. Asandh	Nurse.	-	62	62
2. Pehowa	"	-	29	29	Employed for 5½ months. The first nurse that was appointed for 2 months was found demented and did no work.
3. Thanesar	Nurse-dai.	2	8	10	Employed for 4½ months. Friction with staff.
4. Ladwa	Nurse.	1	10	11	Friction with medical officer.
5. Gulha	Nurse-dai.	-	15	15	Small village with a population of 400. A lazy nurse but has promised to do better.
6. Pundri	Nurse.	-	21	21	Well educated nurse. Friction with medical officer. Will do better.
7. Kunjpura	Nurse-dai.	-	4	4	Employed for 6 weeks only. There were 2 changes.
8. Panipat	Do.	1	60	61
9. Kaithal	Do.	-	13	13	There were about 3 changes of nurses in 5 months.
10. Shahabad	Do.	1	28	29
11. Thaska	Do.	2	7	9	A lazy nurse. Has lost her increment. Has promised to do better.
Ahar	Do.	-	50	50
Indri	Do.	-	37	37
Bhagal	Do.	-	26	26
15. Rajaund	Do.	-	56	56
16. Siwan	Do.	-	23	23	Employed for 5½ months. This place is vacant at present.
17. Samalka	Do.	1	12	13	Employed for five months. The first nurse was employed for 2½ months and then dispensed with as she observed purdah.
			67	67

districts may utilise the whole of the scholarships allotted, whereas others may not be successful at all. When the supply equals the demand, things will adjust themselves, it will then be time to reduce gradually the attractions by cutting down the number and amount of scholarships.

The pay of the old army of indigenous dais can be reduced also and a new army trained and engaged on a lower wage.

If we have rural dispensaries within a radius of 2½ miles, with a qualified dai in each, it will meet the needs of the people for the present, to a large extent, and save thousands of lives.

Current Topics.

Quinine Troposan in the Treatment of Chronic Benign Tertian Malaria.

By J. A. SINTON,

MAJOR, I.M.S.,

W. BIRD,

MAJOR, R.A.M.C.,

and

W. B. F. ORR,

CAPTAIN, R.A.M.C.

(*The Ind. Journ. Med. Res.*, Vol. XVI, Oct. 1928, p. 333.)

ENCOURAGED by the effects of quinine-stovarsol in benign tertian malaria, Messrs. May and Baker, Ltd., London, have produced a new arsenical compound, quinine-troposan, which they have kindly sent us for trial.

This drug is the quinine salt of 2-oxy-5-acetylaminophenyl-arsenic acid and so is closely allied to quinine-stovarsol.

The makers have tested its toxicity on mice and find that troposan is only about half as toxic as stovarsol in these animals. Tested against infections of *T. equiperdum* in mice the ratio of minimum toxic dose to minimum curative dose was found to be 1 to 100 as compared with 1 to 11.3 in the case of stovarsol.

The drug was tested on British soldiers suffering from chronic benign tertian malaria. These patients were treated under the same conditions as already fully described in other articles of this series. The methods of control, detection of relapse, etc., were similar to those detailed previously.

In all cases, the disease was diagnosed by the finding of *P. vivax* in the peripheral blood immediately before the commencement of treatment. A preliminary purgation with calomel and magnesium sulphate was given to each patient before the commencement of all forms of treatment.

The treatments were divided into groups as follows:—

I. *Test Treatments*.—(a) Quinine-troposan (QT. 1) and (b) Quinine-troposan (QT. 2).

II. *Control Treatments*.—(a) Plasmogquine (PM.); (b) Plasmogquine compound (PMC.) and (c) Quinine (QAT.).

Test Treatments.

Quinine-troposan was administered in tablets of 0.2 grm. each. These tablets contained the drug in the proportion of 50 per cent. quinine and 40 per cent. troposan.

(a) *Treatment QT. 1*.—Patients undergoing this treatment were given three tablets of quinine-troposan twice daily for a period of 28 days. This is equivalent to a daily dose of 0.6 grm. (9.3 grains) troposan and 0.75 grm. (11.6 grains) quinine. The total amount given to each patient during 28 days was 16.8 grms. (260 grains) troposan and 21 grms. (324 grains) quinine.

(b) *Treatment QT. 2*.—On account of the absence of any toxic symptoms following treatment QT. 1 and of the lower toxicity of the drug as compared with stovarsol, the dosage was increased. The patients in this series received three tablets thrice daily for 14 days and three tablets twice daily for the next 7 days. The initial dosage was, therefore, 0.9 grm. (13.8 grains) troposan and 1.125 grm. (17.3 grains) quinine daily for 14 days, followed by a dosage similar to that in treatment QT. 1 for another week. The total amount of drug given each patient was the same in the two treatments.

In both these treatments, 60 grains (4 grms.) of magnesium sulphate was given each morning before the administration of treatment, to promote free elimination of arsenic. One ounce of mist. alkali (sod. bicarb 60 grains, calcium carb. 2½ grains, sod. citrate 40 grains and water to 1 ounce) was given before each dose of the drug to protect the kidneys. In addition 15 drms. (60 grms.) of sugar in solution was also given before each dose to protect the liver. These are the precautions already described for the prevention of poisoning by the newer arsenical compounds. The last 24 patients in treatment QT. 2, only received the sugar mixture on one occasion and no ill effects were noticed.

Control Treatments.

(a) *Treatment PM.*—These patients received 0.08 grm. plasmogquine daily until the treatment had been given on 28 days. The treatment has been fully described in a previous article.

(b) *Treatment PMC.*—In this treatment the dosage was ten pills of plasmogquine compound daily until 28 days of treatment were completed. This corresponds to 0.10 grm. plasmogquine and 1.25 grm. (19 grains) quinine daily. Fuller details are given in the paper previously mentioned. These two control treatments were carried out at the same time as treatment QT. 1.

(c) *Treatment QAT.*—These patients were given 0.78 grm. (12 grains) quinine sulphate twice daily in a solution made with citric acid and flavoured with chocolate. The quinine treatment was continued for 14 days, total 21.7 grms. (or 336 grains) quinine and was followed by an iron and arsenic tonic for 7 days. This treatment is on the lines of that recommended for the Army in India. The treatment was used as a control for treatment QT. 2, but as about 40 per cent. of the patients could not be followed afterwards by blood examination, on account of Service difficulties, its value as a control is greatly diminished.

Effects of Treatment in Preventing Relapses.

Test Treatments.—(a) *Treatment QT. 1*.—Twenty patients were given this treatment and of these one was lost sight of after seven weeks' observation, ten relapsed, and nine completed observation without relapse. The relapse was, therefore, a possible maximum of 55 per cent. with an observed minimum of 50 per cent.

(b) *Treatment QT. 2*.—Forty-four patients were treated by this method. Thirty-eight of these were observed by weekly blood examinations and of these fourteen relapsed and twenty-two completed observation without relapse. The other two patients were observed by blood examination for seven weeks only, but had no history of relapse up to three months after this time, i.e., nearly 5 months after completion of treatment. Six other patients were treated by this method but were only observed by blood examination for a couple of weeks. The later histories of five of these six patients were obtained, and in only one case was a relapse recorded up to the end of over three months after the finish of treatment.

The observed minimum relapse rate among the 38 patients of this series was 37 per cent. with a possible maximum of 42 per cent. If the patients observed by clinical methods only are included, the rates are 34 and 36 per cent. respectively.

The possible maximum relapse rate among the 58 patients observed by blood examination, after treatment with quinine-troposan, was 46 per cent. and the observed minimum 41 per cent.

Control Treatments.—(a) *Treatment PM.*—Of the twenty-two patients in this group, two were unable to

stand the treatment and three others relapsed after the treatment finished. The failure rate was, therefore, 22 per cent.

(b) *Treatment PMC*.—None of the twenty patients who underwent this treatment were recorded as relapsing but two were only observed by blood examination for 5 and 6 weeks respectively. The after-histories of these two cases showed no relapse three months later. The relapse rate was a possible maximum of 10 per cent. and an observed minimum of nil.

The observed relapse rate in the 42 cases in these two series was 12 per cent. with a possible maximum of 16.6 per cent. These patients were the control group for treatment QT. 1.

(c) *Treatment QAT*.—There were sixty-eight patients in this series of whom 19 relapsed and 25 were lost sight of before the end of observation. The possible maximum relapse rate was, therefore, 65 per cent. with an observed minimum of 28 per cent. The variations in the estimated relapse rates in this series, due to inability to complete observation, make the results of no great value. However, during the experiments in this enquiry, over 1,100 British patients suffering from chronic benign tertian malaria have been treated under similar conditions with various cinchona alkaloids and the relapse rate among these has been 60 to 70 per cent., which figure serves as a good guide to the average relapse rate after quinine treatment.

Discussion of Results.

The relapse rate observed among the patients treated with quinine-troposan was greater than that seen in the plasmoguinine series, but less than the usual rate seen after treatment with the cinchona alkaloids only. Troposan would, therefore, appear to be a useful adjuvant to these alkaloids.

When quinine-stovarsol was tested in an almost similar dosage to that in treatment QT. 1, the relapse rate was 60 per cent., so quinine-troposan is possibly an improvement on the former drug in the treatment of chronic benign tertian malaria.

Using the more intensive treatment (QT. 2), the possible maximum relapse rate fell from 55 to 42 per cent., as compared with QT. 1, while the minimum rate fell from 50 to 37 per cent. It would seem from these figures that the more intensive treatment gives better results, and it is suggested that the dose of 9 tablets daily might be tried for 21 days or even a more intensive course given. In trying such treatments, it is essential that the precautions mentioned above to prevent arsenical poisoning, should be carried out.

Toxicity of Quinine-Troposan.

The daily dosage of quinine-troposan in treatment QT. 2, corresponds to 0.9 grm. troposan and was continued for 14 days. In our work with stovarsol, the largest dose of that drug given daily over a similar period was 0.64 grm., in the form of the quinine-stovarsol compound. The comparatively larger dose of troposan was well tolerated and no toxic symptoms were observed, although they were with the PM. and the PMC. treatments.

This drug was so well tolerated that it is suggested that a course of 9 tablets (0.9 grm. troposan) daily for 21 days might be tested, to see whether such treatment would reduce the relapse rate still further. Even 12 tablets (1.2 grm. troposan) daily might be tried for a shorter period, but in either case the precautions recommended above to prevent arsenical poisoning, should be carried out.

During the course of this enquiry into the treatment of malaria, over 150 patients have been treated with either stovarsol or troposan, usually in larger doses than those with which other workers record toxic symptoms. Except for one case of slight jaundice after an intravenous injection of 1 grm. sodium stovarsol, we have never seen any deleterious effects after the use of these drugs, although a very careful watch was kept for such manifestations.

The only conclusion we can draw from this fact is that the administration of sugar, alkali and magnesium

sulphate has had a definite preventive action and should always be given when either of these drugs is used.

Conclusions.

Under the conditions of our work, troposan appears to be a very useful adjuvant to quinine in the treatment of chronic benign tertian malaria.

The relapse rate after the use of quinine-troposan was less than that usually seen after the cinchona alkaloids or after quinine-stovarsol, but was greater than after plasmoguinine or plasmoguinine compound.

The drug has been well tolerated over a period of three weeks of continuous treatment, even when given in larger doses than was stovarsol, but prophylactic measures should always be taken against any chance of arsenical poisoning.

The Treatment of Chronic Benign Tertian Malaria with Smalarina Cremonese.

By W. BIRD,

MAJOR, R.A.M.C.

(*The Ind. Journ. Med. Res.*, Vol. XVI, Oct., 1928, p. 347.)

DURING the last few years the Italian physicians have claimed that a new drug—Smalarina Cremonese—is more effective in the treatment of malaria than the cinchona alkaloids, more especially in the chronic benign form.

Cremonese (1925), the originator of this new treatment, claims that quinine acts as a febrifuge only and does not produce a permanent cure of malaria, while Smalarina Cremonese has no febrifuge effects but acts slowly so as to produce eventually a permanent cure. The drug is believed by him to stimulate the organic defences of the body and so produces an immunity, which may persist for two years.

The immediate results claimed for the drug are that during the first month of treatment it produces an interruption of the fever, a reduction in size of the liver and spleen and a disappearance of the pallor and anaemia of the patient. At the same time the patient's appetite returns and his weight increases.

In carrying out the treatment, Cremonese (1925) explains that Smalarina acts slowly and, biologically, has little effect as a febrifuge and that quinine should be given in order to control the fever, while Smalarina should be administered in the intervals when its therapeutic action is best developed. He also considers that its action is most marked in a mild or cold climate.

The ill effects reported after the treatment are diarrhoea, nausea and vomiting, and the contra-indications are nephritis and albuminuria. This new drug is a compound of mercury and antimony. In the early part of the 19th century mercury, in the form of calomel, was prescribed in massive doses for the treatment of ague in India with disastrous results in many cases. Antimony in the form of intravenous injections of tartar emetic was advocated by some workers during the war, but later experiments have failed completely to prove that it has any effect in the cure of malaria.

Methods and Treatment.

Since conflicting reports have been made on the efficacy of the treatment of malaria with Smalarina, it was thought that a few carefully observed trials with this drug might evaluate its worth amongst drugs that have been used in the treatment of malaria.

The trials were carried out during the season recommended by Cremonese, namely, September to May, in a hill station in India where reinfection could be excluded. The patients used in the trials were standardised, that is, they were the same as regards physique, age, diet, clothing, housing, mode of life and environment, and were subjected to the same changing conditions of climate. All of them were young British soldiers who had resided in malarious localities for an average period of three years, and all were suffering from chronic relapsing benign tertian malaria.

Procedure.—One tablet of Smalarina was taken on the first day, two on the third, three on the fifth, etc., one additional tablet being taken every other day, until the 31st day when 16 tablets were taken in one dose. The total dosage was 136 tablets in 31 days. Six cases of benign tertian malaria have been treated in this manner. The blood was examined daily in all cases by the thick film method.

Effects of Treatment in Preventing Relapse.

Relapses were diagnosed by the finding of malaria parasites in the peripheral blood by the thick film method of examination, during an observation period of eight weeks after the end of all treatment. Patients who did not relapse during this period were considered as cured.

Amongst the Smalarina cases the average number of previously recorded relapses per patient was 5.7. The spleen rate before treatment was 33.3 per cent.

Six patients were treated with Smalarina, amongst whom relapses due to *P. vivax* were detected in two during the observation period. Of the remaining four patients none relapsed during observation periods of 8, 9, 11 and 13 weeks respectively. The relapse rate for this group was, therefore, 33.3 per cent.

Effects of Smalarina on the Clinical Manifestations.

A. Clinical Cure.—Smalarina is extremely slow in producing a clinical cure in chronic benign tertian malaria. In the two cases that relapsed, it seemed to have no effect whatever on the parasites in the peripheral blood even during treatment. In one of these relapse cases the peripheral blood was examined daily for a period of over four weeks after the end of treatment, and showed malaria parasites fairly constantly throughout this period, while in those four cases which did not relapse after the end of treatment parasites persisted in the peripheral circulation for an average period of 19.5 days during treatment. After the end of Smalarina treatment parasites were absent from the peripheral blood for an average period of 6.8 weeks, reckoning cured cases as 8 weeks only.

B. Temperature.—The average "duration of fever" amongst the Smalarina cases was 3.85 days (maximum 14 days) as compared with 0.29 days (maximum one day) with cinchonidine sulphate and chocolate controls treated at the same time, and as compared with an average of 0.3 days amongst over 400 cases of benign tertian malaria treated at various times with quinine sulphate. No rise of temperature after the commencement of treatment was observed in two cases only. Amongst the Smalarina cases one developed a rigor within 24 hours of the commencement of treatment.

C. Splenic Enlargement.—Amongst the Smalarina cases the spleen was enlarged in two cases before treatment, in five cases at the end of one week's treatment and in two at the end of treatment.

D. Toxic Effects.—No toxic effects were noticed in any of the cases recorded in this paper. The urines of the Smalarina cases were examined at intervals during treatment for albumin, but none was found in any of the cases. Smalarina was perfectly well tolerated in every case.

Conclusions.

As a result of the trial of Smalarina Cremonese in chronic benign tertian malaria, it was found that this drug has little effect in causing the parasites to disappear from the peripheral blood. For this reason patients treated by this method may act as carriers even while treatment is in progress, which is a very serious drawback. The percentage of relapse in these cases was very low, and these results seemed promising, but too few cases were treated to arrive at any definite conclusion in this respect.

The treatment seemed to have little effect on clinical symptoms, nor were its effects on splenic enlargement more marked than those of quinine.

Urea-Stibamine: Its Preparation and Composition.

By SUDHAMOY GHOSH, D.Sc., F.R.S.E.,
R. N. CHOPRA, M.A., M.D. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

and

NIHAR RANJAN CHATTERJEE, M.Sc.

(*The Ind. Journ. Med. Res.*, Vol. XVI, Oct. 1928, p. 461.)

This work was undertaken at the instance of the Indian Research Fund Association who requested us to work out in detail the method of preparation of urea-stibamine and also the approximate cost of its production.

We first attempted to prepare urea-stibamine by closely following the directions given by Brahmachari. We found that, even with great care, the substance could be obtained only in a very poor yield by following these directions.

The preparation involves the following five stages:—

(1) Preparation of sodium antimonite; (2) diazotisation of *p*-amino-acetanilide; (3) coupling of the diazo solution with sodium antimonite and the formation of stibacetin; (4) hydrolysis of stibacetin to prepare *p*-amino-phenyl stibinic acid, and (5) combination of *p*-amino-phenyl-stibinic acid with urea.

The processes (1), (2), (3) and (4) are described in Von-Heyden's patents Nos. D.R.P. 254421 and 270488 in Morgan's Organic Compounds of Arsenic and Antimony, pp. 313-315 and Brahmachari's paper, "Further details of the preparation of urea-stibamine," is merely a repetition of the description of Von-Heyden's patents. By following the above processes, a very poor yield is obtained. We have been able to work out certain details by which the yield can be much increased. The time at the disposal of the authors was not, however, sufficient to work out all the conditions for getting the maximum yield of urea-stibamine for commercial purposes. In the last process, viz., the combination of *p*-amino-phenyl-stibinic acid with urea, which is essentially Brahmachari's own discovery, the descriptions are all vague and scanty. It is stated that urea is added to the suspension of *p*-amino-phenyl-stibinic acid in water until the whole is dissolved, but it was found by us that the amount of urea necessary to dissolve the *p*-amino-phenyl-stibinic acid is far in excess of the theoretical amount required by the formula suggested. The constitution suggested has also been adversely criticised by Dr. T. A. Henry as follows:—

"When urea-stibamine was first described in 1922 it was regarded as a salt of urea and *p*-amino-phenyl-stibinic acid having the empirical composition $C_7H_7O_4N_2Sb$. Further analysis shows that the formula is correct with the exception that the material contains in addition a molecule of water. Study of the reactions of the substance, however, indicates that it is not a simple salt of the two components as originally supposed, and it is now suggested that in its preparation (which is not described, but appears to involve the heating of urea with *p*-amino-phenyl-stibinic acid) the urea undergoes at least momentary reversion to ammonium cyanate, which then dissociates, the ammonium radicle joining with a hydroxyl group of the stibinic acid residue, while the cyanic acid radicle attaches itself to what was the amino group of the *p*-amino-phenyl-stibinic acid.

Organic chemists will be interested in these singular reactions.

Stibamine, which is the sodium salt of *p*-amino-phenyl-stibinic acid, is now shown to have the trimolecular formula, less two molecules of water, but the author's attempts to write it correctly are not successful. Urea-stibamine and sodium glycyl-*p*-amino-phenyl-stibinate (which it may be explained is amino-stibacetin) do not polymerise."

It is thus doubtful if urea-stibamine is a chemical compound of the type suggested by Brahmachari. It may simply be a complex salt of *p*-amino-phenyl-stibinic acid with urea, having an excess of urea in almost all the commercial samples.

These considerations led us to carry out further experiments on the nature of urea-stibamine. Samples of different brands of the drug available in the market were procured for our analysis.

Discussion of Results.

Firstly, the extraction with a mixture of alcohol and ether showed that most of the urea could be dissolved out by the solvent. Urea-stibamine, which is said to be practically insoluble in alcohol, should be still less soluble in alcohol and ether and the very high percentage of soluble matter in some of the samples casts serious doubts on their purity.

The residues from the above washings, which were soluble in water, did not agree in composition (as regards N. or Sb.) either with *p*-amino-phenyl-stibinic acid or with the formula suggested for urea-stibamine, and this fact also corroborates our view of the nature of urea-stibamine. The varying results with the residues may be partly due to the fact that *p*-amino-phenyl-stibinic acid or its salt is not carefully purified before it is finally combined with urea.

The estimations of urea by hypobromite also showed wide divergences in the urea content of different samples.

Secondly, the estimations of total nitrogen by combustion showed wide variations. The latest formula suggested should have a nitrogen content of 12.3 per cent. and if we assume that the substance (at least some samples) has been prepared properly and that it is a definite compound, it is difficult to account for the results obtained.

Thirdly, the antimony content has been found to vary in different brands of urea-stibamine from 20 to 43 per cent. whereas the content according to the latest formula suggested is about 35.6 per cent. These unusual variations of the antimony content in the different samples show that there is no standard for this preparation and people may be using samples having nearly 50 per cent. of free urea. Untrained manufacturers will thus soon help to ruin its reputation unless a standard is insisted upon. As there is every reason to believe that antimony (in some form) is responsible for the curative properties of the drug, we are of opinion that a standard should be laid down for the minimum and maximum antimony content of the batches of the drug put on the market.

Conclusions.

(1) The different steps in the preparation of urea-stibamine are given in detail to enable anyone to take up its manufacture. The approximate working cost has also been worked out.

(2) Most of the free urea can be washed out in the cold with a mixture of absolute alcohol and dry ether. The nature of the residue left behind casts serious doubts on the possibility of urea-stibamine being a compound of the nature suggested by its discoverer.

(3) The estimations of nitrogen by combustion show wide divergences in the composition of substances sold as urea-stibamine.

(4) The estimations of the antimony content of various samples on the market show wide variations. As there is every reason to believe that antimony (in some form) is responsible for the curative properties of the drug, it is strongly urged that a standard should be laid down for the maximum and minimum antimony content of the various brands of urea-stibamine offered for sale on the market.

Impressions of the Nature of Pernicious Anæmia in the Light of the newer Knowledge.

By J. H. MEANS, M.D.,

and

WYMAN RICHARDSON, M.D. (Boston).

(*Journ. Amer. Med. Assn.*, Sept. 29, 1928, p. 923.)

MINOT and his collaborators have not only shown how a specific anti-pernicious-anæmia body may be isolated

from the liver but have been largely responsible for the idea that this organ contains such a substance as well.

It has been our privilege, since Dr. Minot first told us of the discovery, to observe the effect first of the Minot-Murphy diet, and later of the Cohn-Minot liver extract, in quite a large series of patients with pernicious anæmia in the wards of the Massachusetts General Hospital. Our experience coincides presumably with that of all those who have properly used these methods; namely, that raw liver, cooked liver, or active fractions of liver, or raw or cooked kidney, if given in adequate amounts, cause in practically all cases of pernicious anæmia a rapid remission and restoration to an essentially normal status of blood balance. The improvement is startling and is manifest in a few days in the mental and physical condition of the patient and in the blood picture. Transfusions at their best never effected more dramatic rescues from the brink of the grave than have a few glasses of liver pulp. The characteristic changes that take place in the blood picture are, first, a brief leukocyte rise, then a marked but also brief reticulocyte rise, and finally a steady climb in the red cell count and hæmoglobin to normal levels. There is a tendency for the hæmoglobin to lag behind the red count. We have observed these phenomena now in sixty-five cases. The speed and intensity of the reaction are related to the dose of anti-pernicious-anæmia substance and to the blood level at the start of treatment. As a rule, with raw liver or active fraction, reticulocyte peak occurs between the fourth and the tenth days, and varies between 8 and 56 per cent., with an average of 20 per cent. The rate of red cell increase is from a fourth of a million to a million and a half a week, with an average of 700,000. None of the patients who have continued to take the treatment as prescribed have had a relapse.

The value of liver in promoting blood regeneration in an experimental, chronic anæmia due to blood loss was, of course, proved by the work of Whipple, and it doubtless occurred to many when this work first appeared that a little liver now and then would be a good thing to include in the dietary of the patient with anæmia. Minot, however, took the hint of Whipple's work seriously to heart and went at liver feeding, using large quantities in an entirely scientific manner.

The expectation, in view of Whipple's results, was that liver feeding, if effective at all in human anæmia, would be effective in the secondary type, although Whipple himself stated in 1925 that "even in the complex anemias (human pernicious anæmia, anæmia with nephritis and cancer cachexia) food factors deserve serious consideration in the clinical management of the blood condition." Minot also for some years had had certain notions about the possible rôle of dietary errors in the genesis of pernicious anæmia. These were stimulated, in part at least, by an opinion expressed to him by the late Dr. J. H. Wright, that the primary lesion of pernicious anæmia was in the marrow, and that it resembled a tumour. This led Minot to look elsewhere than in the increased blood destruction for the cause of the disease. The difficulty seemed to lie rather in the failure of the red cell elements to undergo normal maturation. This raised the question of growth promoting factors, and the work of E. V. McCallum, together with certain symptomatic resemblances between sprue, pellagra and pernicious anæmia, the already known beneficial effects of liver soup in the first of these, and finally, Whipple's work all served to focus Minot's attention on liver. Most fortunately, therefore, when he began his intensive liver feeding he included patients with pernicious as well as secondary anæmia. And then the miracle occurred, the reverse of what most persons would have expected: namely, that whereas the patients with secondary anæmia showed an improvement slow and uncertain, those with pernicious anæmia, without exception, showed a rapid and certain one. The response was no less dramatic than that evoked by thyroid in myxœdema, orange juice in scurvy, pituitary in diabetes insipidus, or insulin in diabetes mellitus. By analogy, the conclusion was inescapable that in liver there occurs a substance quite as specific in its effects as are any of the known vitamins or autacoids, the lack

of which in sufficient quantity or form is responsible for most of the manifestations and derangements found in the syndrome called pernicious anæmia. The subsequent isolation of such a body in relatively pure form by Cohn proves that this conclusion was correct.

The question now becomes: What does all this tell us about the nature of pernicious anæmia? It would seem fair to assume, in view of the new facts, that pernicious anæmia is in some sense or other a deficiency disease rather than an infectious, toxic or neoplastic one, as had previously been supposed; but it seems doubtful whether pernicious anæmia bears more than a slight resemblance to any of the other deficiencies with which we are familiar.

In the first place, it is clear that it is not a simple avitaminosis like scurvy or beri-beri. It can be shown that the effect of the active liver fractions is not due to any of the known vitamins; but that is not the important point, because it might of course be a new vitamin. The relation of the specific substance to the disease, however, is by no means as simple as in the case of the known avitaminoses. A sufficient shortage of any of the known vitamins will produce the characteristic deficiency syndrome in any previously normal individual. Many persons, however, in fact, most, live habitually on diets which contain an amount of the specific substance quite inadequate to relieve or maintain in normal blood balance a patient with pernicious anæmia, and yet they never develop that disease. One is forced to conclude, therefore, that the appearance of the disease is not due solely to an external shortage of a specific substance necessary to normal life. There must be in persons who develop pernicious anæmia on what would be an adequate diet for the majority of mankind either some internal obstacle to the acquisition of the specific substance or, because of some pre-existing abnormality, an exaggerated requirement for that specific substance. In other words, for the production of the disease it seems likely that there needs must be something wrong with the individual, an hereditary or acquired defect, as well as something wrong with his dietary.

To date, nothing is known of the synthesis of the specific substance. It is found in mammalian liver and kidney, and apparently in avian liver as well. Thus far it has not been discovered in plants, and unless vegetable sources are subsequently found, we are forced to conclude that some animals, at least all such as can live strictly vegetarian existences, are capable of carrying out its synthesis. Whether the human being usually manufactures the whole or a part of the needed amount of the specific substance, or whether he ordinarily derives it all from his food supply, we do not know. If the former, pernicious anæmia might be considered analogous to myxœdema, the requirement for an abnormally large intake of the specific substance being due to a failure of internal production. The eating of liver then would relieve pernicious anæmia precisely as thyroid relieves myxœdema. But such a relationship we can hardly conceive as being the case. For one thing, the known autacoids are manufactured probably each by a single tissue, the parenchyma of one of the several endocrine glands. The anti-pernicious-anæmia body certainly cannot be regarded as an internal secretion of the liver when it occurs in nearly as great concentration in a tissue so different as the kidney. Insulin, to be sure, is found in a variety of tissues, but in very small amounts as compared with the pancreas, and there is good reason to believe that it is made in no other place than in the pancreas. But as to the question of what tissue synthesizes the anti-pernicious-anæmia substance, we are in the dark.

Important evidence bearing on the problem has been provided by the recent work of Castle. This investigator was loath, on the discovery of the specific substance, to abandon the idea that the well-known achylia had some part to play in the genesis of the disease—a deficiency disease, to be sure, but the deficiency due perhaps to a defect in protein splitting dependent on the achylia. Working on this hypothesis, he showed that a response similar to that obtained from feeding liver could be elicited in the majority of patients with pernicious anæmia studied, by the feeding of skeletal muscle

previously digested in a normal human stomach. This relation would be without effect except when subjected to such preliminary treatment. This finding, of course, suggests that the shortage of specific substance, from which the patient with pernicious anæmia suffers, depends rather on his lack of digestive ability than on a failure to manufacture the substance within his tissues, or that a failure of internal manufacture is due to a failure in gastric digestion which must precede it, in order perhaps to supply certain elements necessary to its synthesis. It is conceivable, perhaps, that the person with normal digestive powers can derive from the products of digestion the wherewithal to manufacture the required substance, but that without such digestion it can be obtained by ingestion preformed; and it might be fair to conclude that in the patient with pernicious anæmia there is an obstacle to the provision of the required amount of the specific substance surmountable by providing either (a) an adequate supply of the preformed substance in the food, or (b) a type of digestion by which it, or substances from which it can be made, can be extracted from an ordinary diet.

These various discoveries, therefore, of Whipple, Minot, Cohn and Castle constitute a colossal advance; yet even so we are still ignorant of the cause of pernicious anæmia. One of its features which is by no means entirely clarified by the newer knowledge is the intermittent course. Diseases based on dietary insufficiencies, such as pellagra or rickets, may be intermittent, but in these the ups and downs can be directly traced to alterations in the diet or to the amount of exposure to sunlight. Chronic infections are characteristically intermittent, but the infectious theory of pernicious anæmia is exploded. Allergic phenomena are intermittent, but it will hardly do at the moment to suggest that pernicious anæmia is a form of allergy. Of course, it is possible that infection and diet may play an important rôle in determining the fluctuations in the severity of the disease. We are familiar with the depressing effect of infection on sugar burning capacity in diabetes. It is possible that the upsetting of an extremely unstable balance between blood formation and destruction by either infection or diet change is responsible for the so-called spontaneous remissions and relapses.

Further study is indicated along the lines of both the nature of pernicious anæmia and the biologic and pharmacologic properties of the specific substance. These two lines are by no means identical. That the supply of the specific substance is not the whole story in pernicious anæmia is conceded; that the specific substance has an effect on the human organism other than to hold in abeyance the manifestations of pernicious anæmia is also now proved. For example, it is effective in anæmias other than pernicious but which resemble it; namely, that of fish tapeworm infestation and that of sprue. It also, according to Sabin, accelerates the proliferation of the primitive red cells of the chicken embryo, and, according to Berglund, increases the number of circulating erythrocytes in normal human beings. Whether the substance that is fed is the final product, or whether it is a precursor of the substance the organism finally needs, should be investigated. A comparison of its effects after parenteral administration with those of enteral administration may further clarify the problem. The substance as now isolated appears to be either a nitrogenous base or a simple polypeptide. The methods for studying the substance are more abundant and obvious than those for studying the disease. Light may be shed on the latter by a careful comparison with other chronic diseases of unknown etiology that run an intermittent course.

From present-day evidence, then, we would conclude that:

1. Pernicious anæmia is a chronic disease of unknown etiology, the chief manifestations of which can be held in abeyance so long as adequate amounts of a specific substance, contained abundantly in liver and kidney, are received.

2. The supply of this substance can be rendered adequate in persons suffering from the disease by feeding large quantities of natural foods which contain it (liver or kidney), or active fractions thereof, or perhaps also

through the provision of the means for normal gastric digestion.

3. Shortage of the specific substance is clearly responsible for the abnormalities in the marrow and the blood. The cause of the shortage is not completely known. Castle's work suggests that the gastric defect may play an important rôle.

4. Whether the normal human being requires any extraneous supply of the specific substance or can synthesize what he needs is not yet known. The problem of whether the active substance now found is in the state that the body needs or is merely a necessary building stone, also remains unsolved.

The Modern Treatment of Varicose Veins.

By G. H. COLT, M.A., M.B., B.Ch. (Cantab.), F.R.C.S.

(*Brit. Med. Journ.*, September 22, 1928, p. 525.)

THE passing of the operative treatment of varicose veins may be regarded as a merciful release for the surgeon, but a tribute is due to those who made the modern operative treatment eminently effective in male, and on the whole fairly effective in female, subjects, and so led directly to the success of the injection treatment.

CLINICAL PATHOLOGY OF THE INJECTION METHOD.

There seems to be a general agreement among those who have examined the veins after injection with various solutions that for about the first hour there is no naked-eye change in the endothelium. The vein contracts, and the walls may stick together, giving a splendid result surgically. With some solutions sudden clotting occurs, resulting later in a thick fibrous cord, which takes months to disappear. Gradual thrombosis allows the excess of blood to be slowly removed, and this, surgically speaking, is greatly to be preferred. In twenty-four hours the endothelium is tumefied, and there may or may not be infiltration and peripheral clot. The clot, when formed, is always firmly adherent from the start. In one of V. Meisen's cases it was not separated by strong massage, which is comparable with the degree of molecular adhesion found between an aseptic clot and a piece of dull-gilt wire inserted into an aneurysm. The clot in this case in the recent state has actually to be scraped off the wire. In forty-eight hours the vein is still contracted, the endothelium swollen and covered with fibrinous deposits. In seventy-two hours the endothelium is proliferating strongly. In a week the clot is undergoing organization and the lumen of the vein is greatly narrowed. At this stage one can gauge fairly accurately the most suitable site for the next injection. In a fortnight the clot is well organized. Later it does not soften or degenerate, but becomes a firm fibrous cord. Sir Sidney Alexander suggests that the term "chemosis of the intima" would be better than "endoventitis." The vein may die, the tissues around it may necrose. Both remain aseptic if protected from infection, the dead tissue forming a scab which separates in about six weeks and leaves a slowly healing ulcer; or healing may take place under the scab.

VARIATIONS IN THE EFFECTS.

Douthwaite states that the thrombosis produced by the quinine solution does not spread rapidly, as it may do with the salicylate solution, and that the risk of persistent ulceration from faulty injection is less. Hanschell's experience differs from this, and Hepworth noticed phlebitis extending downwards from the site of injection. Sometimes the walls of the vein adhere at once with immediate and permanent obliteration of the channel; sometimes there is an extensive reaction in both directions from the site of puncture; sometimes no reaction occurs at all, and yet on repeating the injection a week later in the same way a marked reaction occurs. There is, therefore, little doubt that the chief variables—namely, the blood volume and blood current at the site of injection—have a great effect. We know that in a horizontal varicose vein the blood may be moving slowly in either direction, or that it may be stagnant. In the

vertical position, or even raised 45 degrees, the circulation is centrifugal. These facts have been confirmed radiographically. We do not know, and apparently have no certain means of finding out the effect, at any given moment, of the anastomoses close to our point of injection. Although most of those who practise the treatment try to empty the vein of blood after the needle is in the lumen and before making the injection, so as to bathe the endothelium with the concentrated drug, and then either let the patient lie or stand a few minutes, or a pad and bandage is applied, they have no sure knowledge that the injection has not gone quickly into a deeper loop of vein or been rapidly diluted by blood from another channel. It seems to me unnecessary to blame the keeping properties of a solution when these other obvious variables are present. These variables also help to explain the excellence of the results in general, because the injection reaches, though doubtless in a less concentrated form, the smaller tributaries, and especially the anastomotic and perforating branches which join the deep veins. At that moment the dilution becomes excessive. The respiratory change noticed by Barber may also be intimately related to the matter. That we have not got the whole truth yet is also clear from the case recorded by Wilson of the disappearance of a group of varicose veins below the knee six weeks after six punctures had been made for the withdrawal of blood. Sir William Bennett recorded six cases of the spontaneous disappearance of large varicocoeles after injury to them. Both these observations are interesting also in view of the treatment of aneurysm by scratching the inner wall of the sac with a needle, for in such cases the amount of clot formed has been minimal or nil, and no embolism has ever occurred in the absence of sepsis.

The danger of embolism in aseptic cases of varix treated by injection is evidently very small.

A few cases showing various untoward symptoms have been reported and still fewer in which death from embolism occurred.

RESULTS OF THE INJECTION TREATMENT.

It is quite common now to obtain an almost complete obliteration of a valveless internal saphena system after one injection. The procedure is as follows:—

The patient stands on a chair near a table and a single band tourniquet is lightly applied around the upper part of the thigh, to help to prevent the veins from emptying too rapidly during recumbency. The patient then lies down on the table and the vein is entered, preferably above the knee or in the main trunk below the knee; the tourniquet is loosened, the vein is emptied of blood near the needle, and a finger is placed on it above the middle of the thigh; 2 to 6 c.cm., according to the size of the veins, of 30 per cent. sodium salicylate, with 10 per cent. sodium chloride solution (P. D. and Co.), are injected, preferably towards the groin; the limb is elevated to 30 degrees for three seconds, and then the patient rises slowly and stands on the chair. The finger is removed and the charge of solution sweeps downwards into the saphena system. This is painful for half a minute. The patient describes the pain as continuous and stinging, or as cutting, lancinating, or cramplike, and feels it travelling down the leg to the foot. These omens are favourable. By letting the patient lie down at this stage and again elevating the limb for a few seconds the solution may perhaps be tipped back again or kept a little longer in the saphena. Active muscular movement at once sucks the solution away and dilutes it rapidly. No bad effect has been noticed. Sometimes the solution must miss outlying varicose groups because these may require separate injections a week or a fortnight later, when the effect of the first injection has become manifest. At this time also the external saphena system, or the large anastomotic vein from the external to the internal system, which is often present in front, below, or above or behind the knee, may be injected. A week after the first injection the internal saphena system is generally hardening from the middle of the thigh to the lower third of the leg. Exceptions seem to be explicable by the well-known common sites of the chief deep anastomosing channels which dilute the solution.

Taken as a whole this method has answered very well and seems to me to be better than beginning at the distal radicles and working against gravity with multiple injections. The results have been as follows:—

In the first seventeen limbs sixty injections, each of seldom more than 3 c.cm., were used, and one small scab formed. In the next twenty limbs only forty-seven injections were required of 4 to 6 c.cm., seven of which were in a limb in which the excessive blood volume diluted the solution quickly. Three small scabs formed in these limbs. In nearly all the limbs the degree of varicosity was marked and there was an impulse to the ankle on coughing. Tiredness, weight, fullness, and cramp had been the chief symptoms.

In one limb with a vein of small blood volume an injection of 2 c.cm. was sufficient to cure. In one with a large blood volume one of 6½ c.cm. cured. In three limbs with large blood volumes one 5 c.cm. injection cured in each case. In one case an injection of 6 c.cm. cured the internal saphena, and one of 3 c.cm. the external. In another case an injection of 6 c.cm. (and 5 c.cm. for a large cyst) cured. In one instance the walls of an anastomotic vein stuck together with no sign of thrombosis after the introduction of 2½ c.cm. In two cases with large blood volume injections of 5 c.cm. above the knee and 5 c.cm. near the ankle resulted in cure. In one case injections of 6½ c.cm. and 5 c.cm. cured, and in another instance the introduction of 5 c.cm. and 3 c.cm. cured the condition. By cured is meant that the whole of the visible internal saphena system, which was the one chiefly involved, became thrombosed in a week or a fortnight from the middle of the thigh to near the ankle, and that in five weeks there was, for practical purposes, no sign or symptom of the disease.

These results show clearly that the hydrostatic principles of Trendelenburg (Brodie) and the operative indications of Jeannel are the lines along which the injection method should be practised when using salicylate-saline solution. Whether this method is possible with smaller injections such as with the quinine solution, or not, remains to be settled. The larger volume of the salicylate-saline solution is certainly more manageable in this respect and is yielding the results with negligible risk and little inconvenience; results which are so much better than were possible by laborious and somewhat risky operations that operation seems to be no longer justifiable except in certain very isolated cases.

A Fallacy in the "Heat and Acetic Acid Test" for Albumin in Urine.

By H. D. BARNES, B.Sc.

(*Journ. Med. Assn. of South Africa (B. M. A.)*,
October 13, 1928, p. 522.)

As this test has been established for many years, it would seem impossible for anything further to be said regarding it; nevertheless, a point has arisen in my experience which is either not mentioned or is inadequately stressed in text-books.

For the sake of its rapidity, combined with a high sensitivity, the "heat and acetic acid" test is used as a routine qualitative test in this laboratory.

The urine if turbid is shaken with a knife-point of siliceous (Fuller's) earth and filtered; the filtrate is invariably perfectly clear, and very faint traces of albumin can therefore be detected. The clear urine is then heated to boiling in a test-tube, and one drop of 50 per cent. acetic acid added. In case of doubt comparison with a similar tube containing unboiled urine is a considerable help.

In acid urines no difficulty is experienced—the protein is precipitated before the addition of the acid, which merely causes flocculation of the precipitate. If, however, the urine be amphoteric in reaction, the cloudiness obtained on heating is due to phosphates, and redissolves on the addition of the acid. It is at this stage that due caution must be exercised, as the presence of albumin is liable to be overlooked. If several drops of acid are added directly to the hot urine, appreciable quantities of albumin, even though precipitated momen-

tarily, redissolve and so evade detection. This is much more strikingly shown if, in addition to the amphoteric reaction, the specific gravity of the urine be low (1010 or less). In these circumstances, as much albumin as would be reported as a "definite trace" has frequently been observed to redissolve, and give a result which would confidently be reported as negative.

When one considers that the diet recommended to nephritic subjects—liquids and a minimum of protein—is just the one to produce a dilute urine of low acidity, the importance of this point will be realized.

In such books as do note the re-solution of albumin, no mention is made of the fact that it is more pronounced in amphoteric urines. Deficiency of salts is taken to account for the occurrence and addition of strong salt solution suggested in order to overcome the difficulty. Sometimes, however, it is recommended that the urine be made acid before boiling. This procedure is rather to be deprecated, as I consider the disappearance of the phosphates an invaluable check on the quantity of acid required. In passing, it may be noted that these books are usually of the exhaustive type, and not the ones in general use.

To my mind, the simplest means of avoiding this fallacy is to incline the test-tube after boiling, and allow one drop of the acetic acid (which need not be diluted more than 50 per cent.) to fall on the side, and flow slowly into the urine, whilst shaking gently. By this means the acidity of the urine is slowly increased, the precipitate of phosphates is dissolved, after which the milkiness due to the formation of insoluble albumin slowly appears. The addition in similar manner of a second drop of acid sometimes causes an increase in the turbidity, and is necessary to bring about the complete change, when the original reaction was towards the alkaline side.

It is a safe rule to add drops of acid in the manner described until the phosphates have dissolved and then one drop more. If the urine then remains quite clear, it may be concluded that no albumin is present. The whole process should not occupy so much time that the contents of the tube have cooled below the temperature at which albumin is coagulated. Moreover, when the reaction of the urine is strongly alkaline it is advisable to determine, by means of litmus paper, if sufficient acid has been added. Should the reaction still be alkaline, the addition of acid must be continued until a slightly acid reaction is obtained before drawing any conclusions as to the presence or absence of albumin.

Uncommon Ill Effects of Salvarsan Treatment.

By J. O'DONOVAN, M.D.

(*Brit. Med. Journ.*, October 27, 1928, p. 742.)

FATALITIES from salvarsan therapy do not stand in the front of the minds of the present generation of venereal specialists as they did amongst those who first used this drug with trepidation, and hope, in 1911. For when the arsenobenzols were originally introduced their use became associated with a formidable list of ill effects.

Experience has not demonstrated any certain method by which the type of patient unsuitable for salvarsan therapy can be picked out and treated in other ways; neither old age, aneurysm, phthisis, chronic Bright's disease, high blood pressure, nor severe valvular disease of the heart can, in themselves, be considered as contraindications to its use. Ill effects may follow the administration of small doses, they may occur at the beginning, at the middle, or at the completion of a full course of salvarsan treatment. No brand of manufacture seems to be exempt, though at times a run of toxic effects from the use of any one make compels the physician for expediency to omit this temporarily from his armamentarium. It would be wrong to say that these remedies are safe remedies, though I would be the last to express anything but gratitude for their invention.

Dr. E. T. Burke has recently published a treatment of venereal disease (1927), in which four and a half pages are given on untoward effects of salvarsan therapy. The ill effects there referred to are:

"Headache, shivering, vomiting, dyspnoea, palpitation, fainting, and so on. During the actual injection there may be nausea, and vomiting, a feeling of fullness in the throat, a huskiness in the voice; the face may become flushed and the conjunctivæ injected. At times there are severe cramps in the limbs and abdomen, diarrhoea and cardiac distress, and in many of such cases there is undoubtedly a psychological factor at work."

After these immediate reactions Dr. Burke records an intermediate type of general or local urticaria or an œdema of the face and hands. Hæmorrhagic encephalitis is included in this group, which may be rapidly fatal. He states that it seems to occur most frequently among alcoholics. I have seen but one case, and it occurred in an abstemious primipara.

Under the title "delayed reactions" he refers to "exfoliative dermatitis most prone to occur in neurotic patients." Jaundice is the other and last-mentioned untoward effect. This record might, I think, be fairly considered as a minimizing report when contrasted with the following two accounts. The list collated and published by the Salvarsan Committee of the Medical Research Council in 1922 recorded cases of urticaria, discrete erythema, papular erythema, exfoliative dermatitis, pemphigoid eruption, Raynaud's syndrome with gangrene, and purpura, as toxic effects following the employment of arsenobenzol preparations. Mouradian published an appalling list of "accidents." These included cases of intestinal paralysis, serious uterine hæmorrhage, choleric diarrhoea, cephalalgia with migraine, epileptiform convulsions with sensorimotor troubles, febrile icterus, epistaxis, and hæmaturia followed by anuria.

The cases recorded below are outside this list and are of interest because of their gravity and apparent rarity. I feel certain that many cases are lost sight of through the dissociation of clinics from general hospitals or because such ill effects are delayed and the practitioner in attendance is not in touch with the salvarsan administrator.

CASE I.—*Post-salvarsan Melanodermia.*

A dark, well-built man of 50 was infected with syphilis when 17, and was treated then with caustic to the sore and six months' medicine. In 1923 his Wassermann reaction was positive, and he received eleven doses of neosalvarsan between the end of December, 1923, and the middle of January, 1924, from a competent private doctor. After the eleventh injection his skin became so uncomfortable that he changed his doctor. He was sent into the London Hospital on July 1st, 1924, with general erythrodermia and free generalized exfoliation. A differential blood count showed: stained blood leucocytes 14,300 per cmm., polynuclear neutrophils 80.5 per cent., polynuclear eosinophils 2 per cent., small lymphocytes 5 per cent., large lymphocytes 5 per cent., large hvaline cells 8.5 per cent.

By September 18th the exfoliation and redness had disappeared; the patient's skin was smooth but deeply pigmented, as dark as an Indian's: most uniform in the large flexures, but elsewhere on the trunk and limbs were numerous small circular areas of sharply defined white skin.

This condition has been vaguely recorded by two French writers, Goulay and Bouteillier; Goulay says that arsenobenzol erythrodermia leaves some kind of melanodermia, and Bouteillier contrasts the great frequency of exfoliative erythrodermia with the rarity of melanodermia and keratodermia. (See Case II.)

CASE II.—*Post-salvarsan Maculo-melanodermia with Follicular Hyperkeratosis.*

An unmarried French-polisher, aged 26, came to the London Hospital in June, 1927, with a primary syphilitic sore of six weeks' duration, together with inguinal adenitis and a faint macular eruption on the thorax. The Wassermann reaction was positive. He was treated with seven weekly injections of neo-kharsivan; one of 0.6 and six of 0.9 gram. Two weeks after the last injection both legs were red and swollen. He stayed at home until December 19th, giving a history that he had become red, had skinned all over, and had lost a

good deal of his hair. There was now a startling dappled appearance of the skin of his trunk, neck, and upper limbs, due to a macular, non-infiltrated deposit of brownish-black small ovals of pigment. There was no generalized adenitis, no relapse of the primary sore, but over the trunk, thighs, and arms, both in front and behind, was a most profuse development of projecting small uncoloured horny spines protruding from uninflamed pilo-sebaceous orifices. He was admitted to the London Hospital on January 2nd, 1928; since then a very few spines have become reddened, many have developed blackened tips and can be expressed like hardened comedones; in addition, he has developed a moist eczematous plaque on his right wrist, and a small, infiltrated, pink, slightly itching eruption of the right anterior axillary fold.

There are now no condylomata, no buccal lesions, or pigmentation. The patient feels thoroughly well and has a negative Wassermann reaction. There is no arsenic in the urine and no albumin; the total and differential blood counts show no abnormality.

CASE III.—*Multiple Subcutaneous Abscesses Associated with Arsenical Exfoliative Dermatitis.*

A woman, aged 32, attended my clinic at the London Hospital in February, 1927, with a primary sore and several secondary skin lesions. The Wassermann reaction was positive. She was given an intravenous injection of 0.6 gram of neosalvarsan on February 27th, and this was repeated on March 6th, 13th, and 27th.

On April 4th, the patient developed an irritating generalized morbilliform rash, and was given sodium thiosulphate intravenously. She was admitted into hospital. The whole skin gradually became uniformly more thickened, moist, and weeping in the flexures, cracked and scaling elsewhere. There was an abnormal enlargement of glands. There was profuse diarrhoea with occasional blood in the stools, the temperature ranging between 99° and 102° F. The output of urine at times fell below 20 oz. per diem and showed albumin. The patient lay supine in bed in a typhoid state.

During this time a great number of subcutaneous abscesses developed, resembling the "cold abscesses" of tuberculous infections in that there was an absence of any surrounding inflammatory reaction. Over forty of these abscesses were opened, one to two egg-cupfuls of thick blood-stained pus being evacuated from each. Cultures from this pus showed the presence of *Staphylococcus aureus*. This phase extended over three weeks.

Towards the end of May, the patient's condition began steadily to improve, the thickening of the skin diminished, the fissuring and exfoliation abated, and no new abscesses were formed. There was no shedding of hair or nails. On June 12th, she was able to walk unaided; there was only slight scaling of the limbs and round the orbits, and the patient's general condition was sufficiently good to allow of her discharge from the ward, she having rapidly and steadily gained weight. Her appetite remained good throughout the illness, in spite of the fact that on more than one occasion recovery seemed a remote possibility.

CASE IV.—*Cutaneous and Subcutaneous Necroses, Perforation of the Nasal Septum with Arsenical Exfoliative Dermatitis.*

A man, aged 42, a caretaker, had a primary penile sore and generalized rash in 1908, and was treated, when in the navy, with thirteen mercurial injections. His Wassermann reaction was negative in 1920.

On August 16th, 1927, he attended the syphilis clinic of the London Hospital, with a well-defined ulcer on the right leg. The Wassermann reaction was weakly positive. He had four injections of neo-kharsivan, 0.9 gram, at weekly intervals. Six days after the last injection the eyes became puffy, and he developed a universal lividity of the skin. He was admitted into the ward on October 3rd, and treated at once with intravenous sodium thiosulphate. He showed a generalized erythema, puffy face, swollen limbs, and temperature rising daily from 98° to 104° F. in a fortnight. There was no enlargement of the spleen; no bradycardia. The urine showed a trace of albumin; no sugar; deposit—few leucocytes,

epithelial cells, and amorphous urates. No tubercle bacilli were found. Culture showed the presence of *B. proteus*.

Blood examination on October 13th showed stained blood leucocytes 30,000 per c.mm., polynuclear neutrophils 48 per cent., polynuclear eosinophils 41.5 per cent., small lymphocytes 7 per cent., large lymphocytes 1 per cent., large hyaline cells 2.5 per cent.

On November 7th, the patient developed an acute abscess of the neck. A probe was introduced and passed between the skin and the structures of the neck for three inches on the right side. In addition there were gangrenous sloughs on his back and right heel. The nasal septum perforated. The previous day the heel and back were in perfect order. A radiogram taken on December 22nd showed necrosis of the bone of the os calcis. At this time both legs were markedly pigmented. The patient was discharged well on January 3rd, 1928.

CASE V.—Pulmonary Embolism.

This man was first seen on January 21st, 1927, with a primary syphilitic sore. He was treated at the London Hospital with seven weekly injections of novarsenobillon; the last six doses were 0.9 gram. Early in March, he had some irritation of the neck, which he treated with iodine, and on March 6th, he was admitted with exfoliative dermatitis. He became extremely ill with high fever, delirium, and albuminuria; he recovered from this, but his nasal septum perforated. On April 7th, he complained of small boils in the left axilla and right groin. I examined him at 2 p.m. on April 12th, when he seemed fairly well, able to sit up in bed unassisted, tongue moist, pulse 80, regular, and exfoliation confined to the scalp, palms, and feet. At 10 o'clock that night he complained of distress in his chest, he became unconscious, cyanotic, and died within five minutes. No post-mortem examination was permitted, but the symptoms were sufficiently definite of pulmonary embolism from a clot dislodged from the iliac veins.

I have recorded uncommon but important ill effects following the administration of salvarsan remedies for syphilis. The knowledge of these possibilities makes it important that no practitioner should undertake the intravenous salvarsan therapy of syphilis without having facilities for immediate transference of his patients from an ambulatory clinic to a ward. The knowledge of these possibilities must be brought before the attention of the public if public support is to be sought for the compulsory treatment of venereal disease. Otherwise, there will arise a feeling of resentment among the uninstructed should a severe accident or a fatality follow the compulsory administration of these most important but toxic remedies.

Reviews.

HANDBOOK OF PHYSIOLOGY.—By W. D. Halliburton, M.D., LL.D., F.R.C.P., F.R.S. and R. G. S. McDowall, M.B., D.Sc., F.R.C.P. London: John Murray, 1928. Eighteenth Edition. Pp. 902. Illustrated. Price, 18s. net.

PROFESSOR Halliburton's is probably the most famous of all text-books on physiology. It started life in 1848, the original author being Dr. William Senhouse Kirkes, of St. Bartholomew's Hospital, and it was associated with this great medical school from this date until 1896, when the editorship was taken over by Professor Halliburton. In the 32 years during which he has been associated with it the book has gone through eighteen editions and of the first seventeen editions one lakh sixteen thousand copies were sold. Professor Halliburton has now retired from his post at King's College and he has received the help of his successor in the revision and in the production of this most recent edition. The advances which our knowledge of the subject of physiology is at present undergoing are very great, but the complete re-writing

of the book—in the sense that it was re-written by Professor Halliburton thirty-two years ago—is never likely to be necessary, so we hope that, even when he retires from active editorship, his name will be still associated with the title.

The chapter on the nervous system has been re-written and additional information has been given on the subject of the formation of the blood and bile, on blood groups, and on test meals and the polygraph. Recent work on the spleen, on the control of respiration, and on various other matters has been included. To add to a book of this nature, in view of the additions to our knowledge during recent years, is no great achievement, but to cut out unessential matter without impairing the value of the book requires the hand of the master. The present editors have succeeded in this so well that they have actually reduced the size of the book.

We cannot allow the part that the publishers have played to pass unnoticed. The print is large and easy to read, the illustrations and plates are very well produced, yet the book with its nine hundred pages does not form a bulky volume and the price is absurdly low.

It is the text-book *par excellence* for the pre- or post-graduate student.

L. E. N.

DE LAMAR LECTURES. 1926-1927. (The Johns Hopkins University School of Hygiene and Public Health).—By Several Authors. Baltimore: The Williams and Wilkins Co. English Agents: Baillière, Tindall and Cox, London, 1928. Pp. 224. Price, 22s. 6d. net.

A SERIES of popular lectures on personal and public hygiene is arranged each session by the school of hygiene and public health of The Johns Hopkins University.

The object of these lectures is to bring before the public the general facts and points of view of modern hygiene, with the hope that in this way the school may serve as a centre for the distribution of useful knowledge in all matters pertaining to sanitation and preventive medicine.

These lectures are supported from the fund bequeathed to the Medical School by Joseph R. De Lamar, in accordance with the wish expressed in his will "to give to the people of the United States generally the benefits of increased knowledge concerning the prevention of sickness and disease, and also concerning the conservation of health by proper food and diet."

This volume includes the lectures given in the sixth series, during the session 1926-1927, at the school of hygiene and public health.

The lecturers include Professor F. Neufeld of Berlin and Professor Nuttall of Cambridge. The lectures are all on subjects of considerable interest; that on tularæmia constitutes a valuable review of the discovery and of our present knowledge of this disease. The format is of the quality which we usually associate with the name of this well-known firm of publishers.

ERYTHEMA NODOSUM.—By J. O. Symes, M.D. Bristol: John Wright and Sons, 1928. Pp. 72, with illustrations. Price, 5s. net.

THIS is an interesting little monograph on a disease which is rare in this country. The author states that he has not burdened the text with innumerable references to other writers but has written the book mainly round his own experience. This, we think, is a pity. Usually the most valuable part of a monograph is its bibliography; the experience and opinions of a single writer are more suitably expressed as contributions to medical journals. The main theme of this book is the association of tuberculosis with erythema nodosum. One of the strongest arguments for adding against this theory—but in favour of its dealing with theory, the association with rheumatism is familiar with a of the disease in India and in the tropics. The subject and we countries where tuberculosis is prevalent when he says that no argument which immediately brings the ground. we find that the author

"Headache, shivering, vomiting, dyspnoea, palpitation, fainting, and so on. During the actual injection there may be nausea, and vomiting, a feeling of fullness in the throat, a huskiness in the voice; the face may become flushed and the conjunctivæ injected. At times there are severe cramps in the limbs and abdomen, diarrhoea and cardiac distress, and in many of such cases there is undoubtedly a psychological factor at work."

After these immediate reactions Dr. Burke records an intermediate type of general or local urticaria or an oedema of the face and hands. Hæmorrhagic encephalitis is included in this group, which may be rapidly fatal. He states that it seems to occur most frequently among alcoholics. I have seen but one case, and it occurred in an abstemious primipara.

Under the title "delayed reactions" he refers to "exfoliative dermatitis most prone to occur in neurotic patients." Jaundice is the other and last-mentioned untoward effect. This record might, I think, be fairly considered as a minimizing report when contrasted with the following two accounts. The list collated and published by the Salvarsan Committee of the Medical Research Council in 1922 recorded cases of urticaria, discrete erythema, papular erythema, exfoliative dermatitis, pemphigoid eruption, Raynaud's syndrome with gangrene, and purpura, as toxic effects following the employment of arsenobenzol preparations. Mouradian published an appalling list of "accidents." These included cases of intestinal paralysis, serious uterine hæmorrhage, choleric diarrhoea, cephalalgia with migraine, epileptiform convulsions with sensorimotor troubles, febrile icterus, epistaxis, and hæmaturia followed by anuria.

The cases recorded below are outside this list and are of interest because of their gravity and apparent rarity. On June 12th, she was able to walk unaided; there was only slight scaling of the limbs and round the orbits, and the patient's general condition was sufficiently good to allow of her discharge from the ward, she having rapidly and steadily gained weight. Her appetite remained good throughout the illness, in spite of the fact that on more than one occasion recovery seemed a remote possibility.

CASE IV.—*Cutaneous and Subcutaneous Necroses, Perforation of the Nasal Septum with Arsenical Exfoliative Dermatitis.*

A man, aged 42, a caretaker, had a primary penile sore and generalized rash in 1908, and was treated, when in the navy, with thirteen mercurial injections. His Wassermann reaction was negative in 1920.

On August 16th, 1927, he attended the syphilis clinic of the London Hospital, with a well-defined ulcer on the right leg. The Wassermann reaction was weakly positive. He had four injections of neo-kharsivan, 0.9 gram, at weekly intervals. Six days after the last injection the eyes became puffy, and he developed a universal lividity of the skin. He was admitted into the ward on October 3rd, and treated at once with intravenous sodium thiosulphate. He showed a generalized erythema, puffy face, swollen limbs, and temperature rising daily from 98° to 104° F. in a fortnight. There was no enlargement of the spleen; no bradycardia. The urine showed a trace of albumin; no sugar; deposit—few leucocytes,

panhysterectomy is admirably described and illustrated. The author agrees with the other eminent American gynaecologist, Howard Kelly, in condemning vaginal hysterectomy. Operations not usually included in a volume on gynaecology are described, such as kidney, bladder and rectum operations as well as those for various types of hernia.

There is, at the end of the book, a full reference list of the authorities whose works have been consulted.

The publishers are to be congratulated on the handsome binding, clear printing and excellent illustrations.

KALA-AZAR CHIKITSA (IN BENGALI).—By A. K. Mukherjee, M.B. Second Edition. Calcutta: Published by the Manashi Marmabani Karyalaya, 1928. Pp. 178. Price, Rs. 2.

THE second edition of this useful little book, "Kala-azar Chikitsa," has been written by Dr. Arun Kumar Mukherji, M.B., in Bengalee, bringing it up-to-date. Since the first edition appeared considerable advances have been made in the diagnosis and more especially in the treatment of kala-azar. The book is written in a clear Bengalee style and is full of practical hints. It should be most useful to those doctors practising in the mofussil who are better acquainted with Bengalee than with English. It has also the additional advantage of costing only Rs. 2 which should place it within the reach of even the poorest, struggling practitioner.

E. M.

THE TREATMENT OF DIABETES MELLITUS.—By Elliott P. Joslin, M.D. (Harvard), M.A. (Yale). Fourth Edition. London: Henry Kimpton, 1928. Pp. 998. Illustrated. Price, 42s. net.

THE third edition of this well-known and authoritative book on diabetes was reviewed by us about 4 years ago. The present edition is a much larger volume, several chapters having been completely rewritten with a view to assimilate and incorporate the new conceptions, lately formulated, which have changed the outlook, not only as regards the physiology and pathology of diabetes, but also in respect of its treatment.

The complete story of Hedon's depancreatized dog, which the author has so lucidly described with the help of photographs, is a very useful and interesting study, as it established a close correlation with cases of human diabetes, some of which pass through most of the stages gone through by the dog. The importance of careful dietetic restrictions, the close relationship between diet and insulin, the evil effects that follow sudden stoppage of treatment leading to complete coma, and the almost magical effects caused by the resumption of insulin injections and by intravenous injections of sodium bicarbonate (with a view to immediate amelioration of symptoms) have been very vividly shown in the photographs.

The author has devoted 50 pages in section XIII to diabetes in childhood with a record of 395 diabetic children. The chapter on complications in diabetes has been dealt with much more elaborately than in the previous edition and it will prove to be of great value to practitioners.

Professor Joslin's book is a complete up-to-date book of reference on the subject of diabetes and we have no hesitation in saying that it is one of the best books that are at present in the market. It should prove very useful to general practitioners as well as to research workers on the subject of diabetes.

J. P. B.

URINARY ANALYSIS AND DIAGNOSIS BY MICROSCOPICAL AND CHEMICAL EXAMINATION.—By Louis Heitzmann, M.D. Fifth Revised Edition. London: Baillière, Tindall and Cox, 1928. Pp. xvi plus 366, with 131 figures in the text. Price, 22s. 6d. net.

THIS book in one of the best of its kind we possess on the important subject of analysis of urine and has

proved to be very useful and helpful as a work of reference and also as a valuable guide to both clinicians and laboratory workers. The author has embodied in this revised and enlarged edition all up-to-date information about the physiological and pathological aspects of urine, and has furnished us with an additional list of useful tests of practical value for the detection of abnormal constituents with minute details of the technique. The book is profusely illustrated with pictures of deposits of urine drawn directly from nature by the author, the importance of which in arriving at a correct diagnosis of genito-urinary diseases can hardly be over-estimated. The correct identification of the epithelia of the tubes and pelvis of the kidney as well as of the bladder and the genito-urinary passages is often a matter of considerable difficulty even to an experienced analyst. It is the microscopical examination of the urinary deposits which could clear up many obscure cases left undetermined by clinical observations and chemical examination of the urine. The pictures will be most helpful in making a correct diagnosis and prognosis of diseases of the genito-urinary tract. We endorse the view of the author that if microscopical examinations of urine are carried out more carefully than is generally done, even at the present time, uranalysis is bound to become of far greater benefit to both physician and patient than has so far been the case.

The chapter on "Determination of functional efficiency of the kidney" will be found interesting and profitable reading. The renal function tests described therein are of great practical value to the practitioner; they furnish him with a better conception of his patient's general metabolic activities and especially elimination by the kidneys. They likewise indicate the progress as well as the extent of involvement or destruction of kidney tissues in certain disease processes, and are of great importance to the surgeon also. This chapter has been written for the author by Dr. W. T. Dannreuther and forms a useful appendix to the volume.

We strongly recommend the book to all medical practitioners and analysts.

J. P. B.

THE PATHOLOGY, DIAGNOSIS AND TREATMENT OF NEOPLASMS ORIGINATING IN THE WALLS OF THE URINARY BLADDER.—By Lionel R. Fifield, F.R.C.S. (Eng.). London: H. K. Lewis and Company, Ltd., 1928. Pp. xi plus 94, with 6 coloured plates and 6 other illustrations. Price, 7s. 6d. net.

THIS monograph is the essay for which the Buckston Browne Prize was awarded by the Harveian Society. It is composed of three parts—the first deals with papillomata and carcinomata, the second with rare growths of the bladder and the third with transplantation of the divided ureter for carcinoma of the bladder and some experimental research thereon. The author experimented on thirty dogs and cats to determine whether ascending infection following anastomosis of the ureters to the large bowel travelled by way of the lumen or lymphatics and its relationship to stricture at the anastomotic site. He concludes that 60 per cent. of cases of transplantation of the ureters develop ascending infection which extends by the lumen and by the lymphatics and may occur independently of stricture of the lower end of the ureter—the latter results in about 30 per cent. of cases. The coloured plates are good and there is a selected bibliography and a good index at the end of the book.

H. G. A.

DISEASES OF THE BLOOD.—By A. Piney, M.D., M.R.C.P. London: J. A. Churchill. Pp. viii plus 195, with 20 illustrations, 6 in colour. Price, 12s. 6d. net.

THE author apologises in the preface for adding another to the long list of books dealing with the diseases of the blood. We are familiar with a number of books on this important subject and we certainly agree with this author when he says that no other book quite covers the same ground.

The book is much more than a monograph on diseases of the blood. All the common and a number of uncommon diseases of the blood are dealt with, but in addition full details of the methods of examining the blood and excellent descriptions of all the normal and abnormal cells are given.

The book is printed throughout in large clear type on good art paper. There are a large number of plates which include some very fine coloured illustrations. It is a book which will be most useful in the wards and in the laboratory, and we can thoroughly recommend it to both the under-graduate and the post-graduate student.

L. E. N.

DENTAL MEDICINE.—By F. W. Broderick, M.R.C.S., L.R.C.P., L.D.S. (Eng.). London: William Heinemann (Medical Books), Ltd., 1928. Pp. xv plus 364. Price, 21s. net.

IN "Dental Medicine" Mr. Broderick has treated an old subject from an entirely new standpoint. With the help of bio-chemistry and endocrinology he puts forward a new theory to explain the incidence of dental caries and so-called pyorrhœa alveolaris—his suggestion is "that the acid-alkali balance is the bed-rock cause of both dental caries and of pyorrhœa" and his arguments are most convincing.

Mr. Broderick is to be congratulated on the results of many years' arduous and expensive research work, particularly as he has not been supported by the Dental Board of Great Britain, to whom most other research workers are indebted for annual grants. "Dental Medicine" should be read by all dentists; it will prove of great interest also to all physicians and general practitioners, and "help them to attain a more perfect appreciation of the rôle that the teeth play in the preservation of health and perhaps prevent the indiscriminate extraction of these organs."

J. E.

MANUAL OF HYGIENE AND PUBLIC HEALTH.—By Jahan Lal Das, D.P.H. Calcutta: Butterworth and Co. (India), Ltd., 1928. Pp. xx plus 661. Price, Rs. 3-8 net.

WE reviewed the first edition of this book about 3 years ago, and this is the second edition (1928), and in it much new matter has been inserted. The whole subject of hygiene is divided into 28 chapters and 12 appendices, and there are 105 illustrations. The author says in his preface that this manual has been written principally for medical and public health students, by which he means that it is for helping those students who are going up for their M.B. and D.P.H. examinations. This book is the outcome of his long and varied experience in public health work. The author has worked in the Public Health Departments of the Bengal, and Bihar and Orissa Governments and he has rightly placed his experience at the disposal of other workers in this line, to be utilized if they so desire. The author has endeavoured to bring the book up-to-date and to make it as practical as possible. In this attempt he has undoubtedly succeeded to a great extent. For an honest and impartial review we offer a few criticisms and mention certain omissions, which we hope will be useful to the author when bringing out a new edition.

In the first chapter on vital statistics, for the estimation of population the formulæ $P^1 = P + R^n$ in the n th year and $\log. P^1 = \log. P + 10 \log. R$, are both evidently wrong and misleading to students. In the second chapter, "atmosphere" is stated to reach a height of several hundreds of miles above the earth's surface, which is not correct. On the subject of vitiation of air by respiration, in one place it is mentioned that the ill-effects are neither due to increase of carbon dioxide nor to the decrease of oxygen, but to the increase in aqueous vapour and rise in temperature. In this connection a very important factor, viz., the want of movement, or the stagnation of air, has not been mentioned.

In the section on bacteriological examination of water, the definition of the typical *B. coli* given is

obviously taken from foreign text-books, and is evidently incomplete; it will include many hardy sewage bacilli of little importance, while it will exclude some of the useful indicators of fresh sewage pollution. Then again, for the isolation of undoubted *B. coli* derived from sewage from those atypical *B. coli* which are not derived from sewage, the method described is not clear. The author does not say what the positive reaction in the glucose medium is; students will either understand nothing or will take it to mean 'acid and gas production.' It is very important to know whether sewage pollution is of recent date or of remote duration. In up-to-date laboratories in India, after the counting of lactose fermenters as a preliminary test of sewage pollution, a further test is generally made for eliminating non-sewage lactose-fermenters by using certain sugars. This method is not described and there is therefore a likelihood of much confusion being created in students' minds.

The paragraph on the subject of food poisoning is, on the whole, well-written; but the classification into (1) food infection as caused by the bacilli of the Gärtner group, and (2) food toxæmia as represented only by botulism is not strictly correct. The Gärtner bacillus may cause pure infection or pure toxæmia or more commonly both infection and toxæmia. Botulism (or sausage poisoning), is as a rule toxæmic but it is practically unknown in India; it is this toxæmia which is fatal in 50 per cent. of those attacked; the toxæmia of ordinary food poisoning is not so fatal.

On the subject of anti-cholera inoculation, the author gives Haffkine's vaccine and Castellani's mixed vaccine, and ends the paragraph by saying "In practice generally 1 c.c. of Haffkine's prophylactic vaccine is injected with encouraging results." Not a word about the vaccine which is really used, viz., a suspension of dead vibrios!

On the subject of the ætiology of malaria, and on its prophylaxis, contrary statements are made which would naturally create utter confusion in the minds of students. Causes of malaria in a deltaic area are different from causes in a non-deltaic area, and consequently measures of prevention and control are also different. Ricefields in Eastern Bengal are not at all malarious, whereas ricefields in the United Provinces and in Rajputana are very malarious. Efficient drainage in Eastern Bengal is not only impracticable from the engineering point of view, but is positively ruinous both from the public health and agricultural points of view, even if it were possible as an engineering measure. The cultivation of jute and the steeping of jute stalks in stagnant pools and ponds have nothing to do with malaria. The more dirty, stinking and foul a collection of water is, the less the likelihood of anopheles mosquitoes breeding in it.

These are some of the defects in the manual which would be better removed in the next edition.

Looking to the very low price and the vast amount of subject-matter included in a small compass, the manual ought to be welcomed by students of medicine.

R. B. K.

TWO ESSAYS ON ANALYTICAL PSYCHOLOGY.—By C. G. Jung, M.D., LL.D. (Authorized translation by H. G. and C. F. Baynes.) London: Baillière, Tindall and Cox, 1928. Pp. xviii plus 280. Price, 10s. 6d. net.

THE subject-matter of this volume is based on two papers published some years ago under different titles in the "Collected Papers on Analytical Psychology." Let it be stated at once that this work will appeal to a very limited circle, the members of which have a thorough grasp of "advanced" psychology in all its ramifications.

Turning to the essays themselves, the first, entitled "The Unconscious in the Normal and Pathological Mind," opens with a chapter on the origins of psychoanalysis; here is described the epoch-making work of Freud which has exerted, and is exerting, a profound influence on psychology and psycho-pathology. As a result of his researches the influence of mental trauma as the factor of importance in the causation of neurosis

has been very largely replaced by a belief in the presence of a concealed erotic conflict—a disturbance, that is, in the sphere of love, using "love" in the broadest sense—in all cases of neurosis. The author does not find himself in complete agreement with the theories of Freud or of Adler. "It is manifest," he says, "that each has its field of application in those cases which prove the correctness of the theory. As to those cases that cannot be harmonized with it, well—every rule has its exceptions." In particular, Jung points out that the disposable psychical energy which is obtainable by the psycho-analytic technique is of comparatively little value, in that it cannot in many cases be "sublimated" or transferred at pleasure to a rationally chosen object.

One of the most interesting chapters in the book is that entitled "The Personal Unconscious and the Super-personal or Collective Unconscious." The author demonstrates that two levels can be recognised in the unconscious: (a) the personal unconscious, and (b), what he terms the super-personal unconscious or collective unconscious, the latter consisting of "those potentialities of human representations of things as they have always been, inherited through the brain structure from one generation to the next."

In the section on the function of the unconscious we are given a definition of individuation, viz., "a psychological evolutionary process that fulfils the given individual dispositions.....by which a man can create of himself that definite unique being that he feels himself at bottom to be....." It is rather curious to find that Thomas à Kempis expressed the same thought five hundred years ago when he says, "The more a man is united within himself and cometh inwardly simple and pure, the more and higher things doth he understand without labour."

We have only one criticism to offer, and it is not a criticism of the author but of the translator. Jung is undoubtedly one of the greatest of modern scientific thinkers, and by that same token he is the less in need of the somewhat fulsome flattery that the translator has seen fit to accord him in the preface. The translator's remarks on the attitude of the medical profession towards his idol (Jung) are unnecessarily caustic. Medicine is accused of having assimilated Freud and his teachings "exactly in the same way that the Church of Rome digested Francis of Assisi and with no more attention to the point of view of the digested party"; that this "phagocytic action" has not been performed in the case of Jung is attributed to an obtuseness based on materialistic grounds.

Considering that medicine has to deal with the most precious of human possessions, a meed of materialism is perhaps inevitable.

Printing, binding and general get-up of the book are excellent.

J. M. H.

RONTGENOLOGY.—By Alban Kohler. Translated into English from the fifth German edition by A. Turnbull, M.A., B.Sc., M.B., Ch.B. (Glas.). London: Baillière, Tindall and Cox, 1928. Pp. xviii plus 556, with 324 figures. Price, 42s. net.

THE volume in German is the fifth edition of a work originally published in 1910, and that under review is the first English translation. To use Professor Köhler's words, the work is meant to be "an adviser on those findings which exhibit or appear to exhibit slight and not particularly noticeable divergencies from the normal anatomical picture."

The work is well described as a veritable mine of information on everything connected with X-ray examinations. The general plan adopted is first of all to describe the normal appearances, including processes of ossification in the case of bones, and then to discuss the pathological variations from different points of view. Each of the various systems of the body is considered in turn and practically every abnormality or early pathological change that is capable of demonstration by X-rays is considered.

Reproductions of skiagrams are largely replaced by carefully detailed line drawings giving the outline of

the important features. This is an excellent plan and one to be recommended to other writers on the subject. One cannot help observing, however, that the skiagrams reproduced are of poor quality.

The work of translation has been well accomplished, although the style is somewhat stilted. This, of course, is inseparable from the desire to preserve as far as possible the author's idioms and metaphors. On the whole, Dr. Turnbull is to be heartily congratulated.

As a work of reference for the radiological expert this book has no equal. There is no other work which deals with slight departures from the normal and their pathological significance in such detail.

J. A. S.

THE PRACTICE OF REFRACTION.—By W. S. Duke-Elder, M.A., D.Sc., Ph.D. (Lond.), M.D., Ch.B., F.R.C.S. London: J. & A. Churchill, 1928. Pp. xiii plus 410, with 208 illustrations. Price, 12s. 6d. net.

THIS is a really excellent modern book on refraction, rather on the lines of Ernest Clarke's well-known book, but much more modern and scientific in its methods and detail, as might be expected from the previous work of this author.

His explanations on the scientific side are good and clear, and on the practical side he stresses the utility of retinoscopy without a mydriatic and gives many little tips for accurately determining the amount and angle of an astigmatic correction by this method.

This method will prove much more difficult in practice in India, with its bright glare in which we live and work, than in England where, living in a normally dull light, the movements of a bright small spot are much more easily appreciated and consequently the problems of light perception and contrast are different.

The work is thoroughly practical and complete and all interested in the problems of refraction should read it: they will find it a mine of information incorporating much recent work put in a well-balanced way.

W. V. C.

Annual Reports.

THE ROCKEFELLER FOUNDATION, ANNUAL REPORT, 1927. THE ROCKEFELLER FOUNDATION, 61, BROADWAY, NEW YORK.

A GLANCE at the Rockefeller Foundation Annual Report for 1927, which has come to hand, reveals the world-wide activities of this great organisation whose avowed object is the promotion of "the well-being of mankind throughout the world."

Features of interest so far as we in India are concerned are the following:—

MALARIA CAMPAIGN IN CEYLON.

Malaria is a serious public health problem in many parts of Ceylon. An engineer has been lent to the Government by the Foundation to organize a division of sanitary engineering, which should play an important part in anti-malaria operations. One of the men recently trained under a Foundation fellowship has returned to Ceylon to continue his work in malaria. As a result of several years' study of the anophelines of Ceylon, a new vector has been discovered, *A. culicifacies*.

HOOKWORM RESEARCH IN MADRAS.

Under the direction of the Foundation's representative a study of hookworm infection was carried on in the Madras Presidency, India. Newly acquired infections with *Ancylostoma duodenale* were shown to produce much greater damage than is experienced from infections acquired over a long period of time. The fall in the amount of hæmoglobin in the blood was rapid and striking. Studies were under way to determine a longevity curve for hookworms in the intestinal tract. Trials of tetrachlorethylene, a vermifuge which

has been recommended for use in place of carbon tetrachloride, gave encouraging results.

PERMANENT HOOKWORM PROGRAMME MAKING SATISFACTORY PROGRESS IN CEYLON.

The Foundation continued to assist the Government of Ceylon in a hookworm programme by assigning a representative to act as adviser and participate in the administration of the work, and also by contributing toward the expenses of a rural health unit, which is taking over the hookworm work in the area within its jurisdiction. The effort to reduce the prevalence of hookworm disease first in the areas of heaviest infestation was continued. The medical services of various plantations treated the labourers at semi-annual intervals. In addition, hookworm treatment was given to practically all persons applying for medical relief at public hospitals or dispensaries. The total number of hookworm treatments administered in 1927 was 1,573,955 of which 1,039,003 were given by government hospitals and dispensaries. All tea and rubber estates, about 2,000, were offered an opportunity for one day's treatment of their labourers. Of the total 159,431 labourers passing through Mandapam camp on the way from India to Ceylon, 141,720 were treated for hookworm infection.

During the year, 302 latrines were built in villages, bringing the total number constructed since the inauguration of the hookworm campaign up to 6,128; on estates 2,112 new latrines were constructed bringing the total up to 4,182. In the schools of the island 162 latrines were installed during 1927. Educational measures described in previous annual reports of the Foundation were continued during the year. It was arranged for the Department of Medical and Sanitary Services to take over the hookworm campaign at the end of the year and to conduct it in connection with the sanitary division. All the schools in the island have been visited once and some of them twice since the inauguration of the campaign.

INTENSITY SURVEY DEFINES HOOKWORM PROBLEM IN THE MADRAS PRESIDENCY.

The intensity survey of hookworm infection in the Madras Presidency, India, was completed in October, 1927. This survey, which covered twenty-five districts and the Mandapam labour camp, involved 58,017 egg counts and is the most extensive study of this kind undertaken in any part of the world. An analysis of the survey findings has made it possible to define the areas in Madras where hookworm infection is of economic importance. Infection rates vary in different districts from 12 to 94 per cent.; the average for the presidency is 73 per cent. It is shown that infection is acquired at an early age and between the tenth and twentieth years reaches a maximum which is maintained practically throughout life.

The highest average egg count, 1,377 eggs per gram, was found in the Ganjam district. This represents an average of approximately 110 hookworms per person. Ten other districts approached this average, namely, Chingleput, East Godavari, Malabar, Nellore, South Arcot, Tanjore, Trichinopoly, Vizagapatam, West Godavari, and the foothills of the Nilgiris. Since the infestations are chiefly with *Necator americanus*, an average of 100 worms per person is not sufficiently important from an economic point of view to warrant the usual treatment measures. Therefore employment of the so-called mass treatment of hookworm infection is not justified in the Madras Presidency. It is believed that health education, routine treatment of all hospital and dispensary patients, and the promotion of latrine construction will reduce hookworm infection to relative insignificance. The active programme now being developed is based upon these fundamental factors.

To promote a programme of rural sanitation compatible with existing conditions, demonstrations in soil sanitation were continued in the Madura district and initiated in certain estate areas in the Nilgiri district. In Madura, work was considerably extended. Deep pit latrines of the bored-hole type apparently meet the requirements of Indians, as is shown by the

increased use of these conveniences. Three hundred and fifty-one such latrines were constructed in 1927, in response to popular demands. Experience has proved that this type is effective, easily maintained, and economically feasible. It gives promise of solving the soil-pollution problem in areas where suitable terrain conditions prevail. A steel borer has been lent to private enterprises and to the Chingleput District Board to promote similar latrine construction in other communities.

The government health officer appointed to work on estates commenced activities on Nilgiri plantations. Initial efforts have brought about commendable improvement in sanitation, and the favourable reaction of estate labour in the use of sanitary latrines augurs well for the future. Treatments have been administered only in villages or on estates where sanitation was in progress. Towards the end of the year curative work was undertaken among school children in the Madura, Chingleput, and Malabar districts. A total of 24,123 treatments has been given.

Educational work through the media of lectures, demonstrations, films, and charts was carried on in every district in the presidency. Types of latrines suitable for village needs were exhibited at fairs and festivals. In the Madura district important educational work was accomplished by installing a sufficient number of bored-hole latrines to accommodate several thousand pilgrims assembled for religious functions.

Approximately 137,686 persons were reached by lectures and, in addition, the films on hookworm and malaria attracted many thousands of people. All government hospitals and dispensaries are required to treat hookworm infection as a routine measure in accordance with a government regulation effective from April, 1927. This work is developing favourably. Approximately 76,000 treatments were administered during the year. It is anticipated that between a million and a half and two million treatments will be given annually in these institutions.

Plans to administer one treatment each year to school children, led the Government to provide funds to develop a programme of treatment, education, and sanitation in all schools where medical inspection is conducted. Work was initiated in Madura, Chingleput, and Malabar districts by members of the campaign staff who instructed school medical inspectors in treatment technique.

SURVEY OF HEALTH CONDITIONS IN THE NATIVE STATE OF MYSORE, INDIA.

The invitation of the native state of Mysore, India, for a public health survey was accepted, and a member of the field staff sent to direct the work. Efforts are being made to determine the incidence of hookworm infestation and malaria, which are reported to be serious health problems.

By the close of the year the first spleen survey was completed except for some small areas; 8,143 children had been examined, of whom 36.1 per cent. showed enlarged spleens. Of 3,038 persons examined for hookworm infestation, 77.5 per cent. were infected. Egg counts were employed in the case of 2,713 persons, of whom 78.3 per cent. were found positive, with an average egg count of 2,200 eggs per gram.

SUCCESS OF DISTRICT HEALTH WORK IN CEYLON.

The health organization in the Kalutara district of Ceylon continued to function throughout the year. The Government also voted funds to provide two additional health organizations, one of which was established in the Kurungala district in North-Western Province late in 1927. This type of work is now well established and seems to meet the needs of the people of Ceylon.

Four health centres operated in the Kalutara district during the year, two in urban areas and two in rural sections. At one of these, Koholana, established in 1926, the first model child welfare and maternity centre in Ceylon was opened in December, 1927. The site, building, and equipment were provided by public-spirited residents of the community. At Kalamulla a new station was inaugurated to serve a rural area.

Milk stations were conducted in conjunction with all centres, and some progress was made in securing safe milk supplies for the district.

The scope of the activities of the health organization has been extended, and attendance at the clinics has shown a wholesome increase. An outstanding feature of the work has been the development of activities to reduce the high maternal and infant mortalities. During the past year 582 mothers and 448 infants were registered at the health centres, and nurses made 3,231 home visits in their interests. Pre-school children received special care, and more than 1,300 home visits were made to 219 young children enrolled. Medical inspection of all school children in the district was completed.

Intensive health education was associated with all activities undertaken. A special course of lectures was given to teachers in the district by the medical officer of the organization. Elementary instruction in personal hygiene, housing, refuse disposal, and conservancy was prepared for the village headmen. At the conclusion of the course certificates of proficiency were awarded. Illustrated lectures, informal talks to school children, distribution of health pamphlets and personal conferences were utilized. The health survey was completed in March. An intensive hookworm campaign was undertaken and treatments were administered to practically 10 per cent. of the population. Latrine construction has been stimulated. General sanitation in the district as a whole has improved since the establishment of the health organization. The reporting of morbidity and mortality statistics has shown improvement.

RURAL HEALTH DEMONSTRATION IN INDIA.

As a means of introducing a general health programme in the Madura district of the Madras Presidency, India, measures for dealing with the outstanding problem, that of sanitation, were undertaken. A demonstration in rural sanitation which was begun in 1926, was continued and considerably extended during the past year. An active programme of health education was conducted by means of illustrated lectures, school talks, personal conferences, and distribution of health literature. Approximately fifty-nine thousand persons attended the lectures and conferences, which dealt with hookworm disease, soil pollution, village sanitation, personal hygiene, and water-supplies.

THE HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS.

Collaboration with the Health Organization of the League of Nations was continued through the contribution of funds toward international interchanges of public health personnel and the further development of a world-wide service of epidemiological intelligence and public health statistics.

In 1927, the plan of interchanges was broadened to include the organization of two international courses of advanced training in public health and hygiene. The first of these was held in Paris at the Institute of Hygiene of the Faculty of Medicine with twenty-six officers from fifteen health administrations in attendance. The first part of the programme included lectures and visits in Paris and the vicinity to study the practical application of various health measures. During the second part of the course, each of the participants visited two or three countries for the study of problems of outstanding importance.

Nineteen medical officers representing fourteen countries met in London in November, 1927, for the second course of this type. The programme of work included lectures and practical studies of public health institutions and organizations.

Two regular interchanges of health personnel were held in 1927, one in Great Britain and the other in Germany. Twelve officials from the health administrations of ten countries participated in the former; while the latter, the first international interchange to be held in Germany, brought together twenty-five health officers from twenty-one countries. After a preliminary period spent in studying the federal public health services, visits were made to several large towns, a

mining area, watering places, and small communities. Twelve persons from six countries received subsidies for special studies.

The epidemiological and public health intelligence service continued work along the lines described in previous annual reports of the Foundation. In February, 1927, the Foundation renewed for a period of seven years, beginning in 1928, its agreement with this service to promote special activities relating to the advancement and unification of vital and public health statistics. Annual contributions will be made on a decreasing scale.

In order to secure greater uniformity in statistical procedure, a commission of expert statisticians was appointed late in 1926, to consult with various governments about the contemplated revision of the international list of causes of death. The first meeting of this group was held in March, 1927.

A conference on methods of collection, transmission, and publication of epidemiological intelligence on an international scale was held at Geneva. Recommendations were offered for the improvement of the system now in operation.

The epidemiological work of the Eastern Bureau at Singapore continued to expand; by the end of the year 140 ports were furnishing current information on the prevalence of important communicable diseases. Thirty-five health administrations in the Far East have agreed to notify the bureau of the arrival at their ports of ships having on board persons with communicable diseases. The new epidemiological sub-centre at Melbourne, Australia, provided reports on health conditions in the Austral-Pacific Archipelago. The meetings of the advisory council of the bureau in 1927 were attended by thirty-one persons representing thirteen national and colonial administrations.

During the year a grant was made by the Foundation to assist over a seven-year period in organizing a centre of public health documentation at Geneva. The functions of this centre are the collection and dissemination of information regarding public health activities throughout the world.

REPORTS OF THE INFECTIOUS DISEASES HOSPITALS OF BOMBAY CITY FOR THE YEAR 1927. BY P. T. PATEL, M.D. (LOND.), M.R.C.P. (LOND.), D.T.M. & H. (CAMB.), F.C.P.S., MEDICAL SUPERINTENDENT.

THE ARTHUR ROAD HOSPITAL.

THE total number of admissions during the year was 952 as compared with 463 in the year 1926.

The fatality rate for all the diseases was 20 per cent. as compared with 19.4 per cent. last year.

The total number of admissions among European and Anglo-Indian patients was 22 as compared with 8 in the previous year.

They were distributed as follows:—

15 smallpox, 1 measles, 3 cholera and 3 other diseases. Out of 15 smallpox cases 3 were unvaccinated cases with 1 death, and 12 vaccinated cases. Out of 3 cholera cases 2 recovered and 1 died.

Military admissions totalled one only as compared with none last year.

The total number of beds in the Hospital in normal times is 216 (132 Indian and 84 European).

This figure is calculated on an allowance of 100 sq. ft. of floor space per bed. In an emergency the number of beds can be increased.

DISEASES.

Smallpox.—Smallpox prevailed throughout the year. The highest number of admissions was 174 in March.

Vaccination.—There were 726 smallpox patients of whom 372 were unvaccinated and 354 vaccinated.

The Treatment of Smallpox.—The same routine treatment of smallpox as obtained last year, was carried out, but with improved nursing and hydro-therapy, an improvement in the general condition and comfort of the patients was achieved. The serious hæmorrhagic and septic cases are still refractory to treatment although

some of the latter respond to polyvalent serum treatment.

Post-Mortem Examinations.—Three autopsies on cases of hæmorrhagic smallpox were performed and in all cases generalised enlargement of glands and muscular hæmorrhages were found.

Cholera.—There were 88 cholera cases admitted this year as compared with none last year. The highest number of admissions was 63 in July, out of which 47 cases were admitted from Rowli Hill Beggars' Home.

Treatment of Cholera.—The same routine treatment—Rogers'—as last year, with some modifications in special cases was carried out, the mortality rate being 32 per cent. The increase in the mortality rate is explained by the fact that the majority of patients were old crippled and debilitated persons from the Beggars' Home. Still, it compares favourably with 50 to 60 per cent. with the old methods of treatment. All cases were examined bacteriologically, and in 41 positive results were obtained.

A total of 1,036 bacteriological examinations of various kinds was made during the year under review.

Dr. P. T. Patel was in charge of the hospital during the year.

THE MARATHA PLAGUE HOSPITAL.

The total number of admissions during the year was 869 as compared with 655 in the year 1926.

The total daily average number of patients was 34.

Employees from Police and Marine Forces, Convicts and Government Servants.—Admissions among these numbered 46 and the charges recoverable from Government for their treatment amounted to Rs. 1,271-8.

The total number of beds in the Hospital in normal times is 106 of which 80 are permanent while 26 are accommodated in temporary wards.

Two wards containing in all 32 beds have been allotted for the reception of advanced cases of pulmonary tuberculosis.

DISEASES.

Plague.—This year the admission of plague cases was more than double that of last year. The total number of admissions of plague cases was 60.

Buboes were incised in 12 cases and removed in three cases by excision.

A total of 164 bacteriological investigations of material from plague patients was made during the year. Of these some were carried out at the Haffkine Institute, Parel, the remainder at the Arthur Road Hospital.

Cerebro-Spinal Meningitis.—5 cases of cerebro-spinal meningitis were admitted in the whole year and all died. All cases were admitted in a moribund condition, two dying within 4 hours after admission. In all 10 lumbar punctures were performed for diagnosis and treatment. No patient was suitable for a course of intra-thecal serum treatment. Four specimens were examined at the Haffkine Institute, Parel, and at Arthur Road Hospital Laboratory, out of which 3 were positive. Two out of the five cases had secondary pneumonia and one got convulsions as a complication.

Post-Mortem Examinations.—Two post-mortem examinations were performed during the year.

Malaria.—The total number of malaria cases treated during the year was 64 comparing with 75 in the year 1926.

Treatment.—All patients were treated with cinchona febrifuge grs. 10 three times a day in a mixture with intravenous injections of sodii cacodylate grs. 5 to 7½ dissolved in 5 c.c. of distilled water every alternate day. Plasmoquine was tried in a few cases with no better results. On the other hand cyanosis was observed in one case under this treatment after the fever had stopped.

Tuberculosis.—446 cases of advanced tuberculosis of the lungs were admitted for isolation during the year.

32 x-ray examinations of cases of tuberculosis were done at the King Edward VII Memorial Hospital, Parel.

Treatment.—Most of the cases admitted to the hospital were advanced cases of pulmonary tuberculosis so the treatment followed was only symptomatic with complete rest, good nourishment and nursing. In five selected, one-side cases, artificial pneumothorax was induced with some success. No definite conclusions could be drawn from this as the treatment is necessarily very long and the patients do not take the full course.

Besides the above, 434 patients were treated as out-patients as compared with 388 in the previous year.

Dr. P. T. Patel was in charge of the hospital during the year.

ADMINISTRATION REPORT ON THE JAILS OF BIHAR AND ORISSA FOR THE YEAR 1927. BY LT.-COL. G. W. MACONACHIE, M.B., I.M.S., PATNA. SUPDT., GOVERNMENT PRINTING, BIHAR AND ORISSA, 1928. PRICE Rs. 2.

The number of jails and subsidiary jails remained the same as in the previous year, viz., 4 central jails, 12 district jails, one juvenile jail and 50 subsidiary jails.

The prison population of all classes at the commencement of the year was 6,771 against 6,211 in 1926. The number of admissions including transfers was 43,711 which exceeded the previous year's figure by 4,980, while the number of prisoners discharged from all causes also showed an increase, being 42,623 against 38,171 in the previous year. The increase in admissions contributed to a larger population at the close of the year, which was higher by 1,088 than that at the end of the year 1926.

The total of the daily average number of each class of prisoners showed an increase of 957.61 as compared with the previous year.

The daily average number of convicts rose from 5,488.76 in 1926 to 6,264.52 in the year under report.

Owing to overcrowding in the Sind jails of the Bombay Presidency, the Government of Bihar and Orissa agreed to take over 50 Beluchistan prisoners from that presidency, and out of these, 46 were received towards the latter part of the year.

Crimes.—There was a further increase in the total number of offences, the figure being 14,523 against 13,009 in 1926. The number of offences against the person as also those against property increased from 1,915 and 5,481, respectively, in 1926 to 2,174 and 5,975, in the year under report. There was an increase in the number of crimes of a serious nature, such as "murder and attempt to murder," "culpable homicide and attempt to commit the same," "attempt to commit suicide," "rape" and "dacoity."

Of the 14,523 convicts received by direct committal, 74.53 per cent. were Hindus, 13.41 per cent. Muhammadans, 0.44 per cent. Christians and 11.62 per cent. other classes. As compared with the figures of the preceding year, the percentages of Muhammadans and other classes, viz., 12.33 and 9.51, have increased while those of Hindus and Christians, viz., 77.24 and 0.91, have decreased. These figures show little variation from year to year and the slight rise or fall is generally due to events which it is not possible to explain.

All prisoners are allowed reasonable facilities to observe their religious practices. Religious and moral instruction is also imparted to the prisoners by voluntary workers and the services of these gentlemen appear to be appreciated.

As usual, persons between the ages of 22 and 40 years contributed the largest proportion of the prison population.

The number of literate convicts was 12.82 per cent. of the total admissions, while that of illiterates was 87.18 per cent. The figures for the previous year were 13.16 and 86.84, respectively.

Compulsory education for all prisoners of 25 years of age and under was continued in the Gaya central jail throughout the year. There were 58 prisoners of this class at the beginning of the year and 54 were admitted to the class during the year, making a total of 112 prisoners. With the exception of 7 prisoners all were illiterate on admission. The number in the class at the close of the year was 84.

These prisoners were taught all the subjects prescribed for the upper primary class by the Education Department and the progress made was most satisfactory. Seven of the boys have already finished their course of class IV of the upper primary standard and 6 have completed the full lower primary course and have been promoted to the upper primary class.

In view of the satisfactory progress made during the experimental period, Government have sanctioned the scheme being made permanent and have lowered the minimum limit of sentence for admission to the class for adolescents at that jail from 2 years to 1 year. Government were also pleased to sanction a third teacher for the school on a pay of Rs. 15—1—20 a month.

The teaching of manual labour and physical drill along with the school work was continued, and the good effect noticed last year on the behaviour and morale of the pupils was again evident.

The question of extending the system of compulsory education to other central jails is under consideration and proposals will be submitted to Government in due course.

An examination of the figures for this and the previous year shows that there was an appreciable increase in the number of persons engaged in agriculture and those following miscellaneous occupations. These two heads account for an increase of 1,205 admissions out of the total increase of 1,514.

The number of female convicts imprisoned during the year was 548 against 461 in the previous year. Their daily average number for the year was 169.09 against 145.69 in 1926.

The total number of youthful offenders and juveniles, i.e., all prisoners up to 20 years of age, admitted during the year, was 989 against 742 in 1926. Of these, 65 juveniles, viz., 63 boys and 2 girls, were under 15 years of age as compared with 49 boys and 7 girls in the previous year.

Juvenile Jail.—There were 168 boys in the juvenile jail in the beginning of the year, 55 were received from the local courts, 278 from jails and subsidiary jails of the province, and 1 from outside the province, making a total of 502 dealt with during the year. Of these, 33 were transferred to other jails to undergo sentence, 286 were released, including 9 released on license under orders of Government, 2 were sent to the Reformatory School and 1 was transferred to the Mental Hospital, leaving 180 juveniles in confinement at the close of the year. The daily average population for the year was 160.89 against 141.18 in 1926.

The percentages of length of sentence of the boys dealt with in this institution during the year are shown below:—

One year and under	..	81.27
Above one year and not exceeding 2 years	..	7.57
Over two years	..	11.16

From the above it will appear that the percentage of short term boys is excessively high and no permanent or substantial improvement is to be hoped for in the character of a juvenile prisoner, unless he is detained in custody for a period sufficiently long for the authorities to acquire some understanding of and hold over his character and to enable them to inculcate habits of discipline, obedience and work. This, however, is not possible unless a Borstal Act is passed empowering magistrates to award at least 3 to 5 years' detention in a Borstal Institution in lieu of a short term of imprisonment. Detailed proposals were submitted to Government after the close of the year for establishing a Borstal Institution in this province and the question is now under the consideration of Government.

The number of youths admitted to jail, as well as the number of adult prisoners, is showing a disquieting increase year by year. It is evident that the punishments inflicted on juvenile delinquents have no sufficient deterrent effect, and the larger the number dealt with in this ineffective manner the greater is the number of youths who will have lost their fear of jail and who will be ready to swell the numbers of the adult and habitual criminal classes.

Youths not obviously weak minded who exhibit anti-social conduct are, as a rule, weak willed or are idle and badly trained, or are deficient in moral sense or in wisdom, or in both. The badly trained and the deficient in moral sense, in the absence of suitable control and training or a sound system of probation, tend to come to jail, and if, in the jail, the punishment inflicted is not deterrent, obviously it is not made clear to them that it is better to keep within bounds and no inhibitory influence is brought to bear upon their moral deficiency. They are, therefore, likely to offend again, and if, in addition, they are defective in the faculty of wisdom and unable to profit by experience and to see things in their true perspective, all the elements exist for the production of habitual criminals. It is desirable, therefore, to inflict sentences which will tend to produce some impression and allow time for influence and training. The weak willed and the defective in wisdom are pathological and can only be dealt with successfully by continuous control.

About 14 per cent. of the boys are found to be of weak mind and it is probable that with adequate examination a much larger number would be found to be abnormal in some respect. The presence of these no doubt complicates the work of the jail school, but the best method of meeting this difficulty is not easy to arrive at, necessitating special examination and special methods of education.

The daily average number of boys employed in different technical classes was 110.65. The main industries were carpentry, blacksmithy and tinsmithy, and the daily average number of boys employed on these industries was 78.79.

Night school continued during the whole of the year and was very useful to the boys. Religious and moral instruction was imparted to them throughout the year by the Hindu and Muhammadan ministers twice a week. Every facility was afforded to the boys of different religions to attend to their prayers and religious exercises.

As poor boys on release are unable to start whatever industries they may have learnt in jail, Government have sanctioned the proposal to provide such boys on release with tools at a cost not exceeding Rs. 10 per head, with a view to enabling them to earn a livelihood after release.

In view, however, of the total indifference of the public and frequently of the parents of these boys as to what becomes of them on release, it is not easy to ensure that this help is usefully or profitably employed.

On the 1st January, 1927, there were 18 civil prisoners in the jails of the province. Two hundred and nineteen were received during the year, making a total of 237. Of these, 212 were discharged, leaving 25 in confinement at the close of the year. The daily average number was 22.83 against 19.45 in 1926.

Three detenues received from Bengal were in confinement at the beginning of the year. Two more detenues were received from Bengal during the year, making a total of 5. One of them was released and 2 were transferred to Bengal during the year, leaving 2 in confinement at the close of the year.

The number of non-criminal lunatics sent to jails for observation was almost the same as in the preceding year, viz., 50 against 51 in 1926.

The number of escapes fell from 16 in 1926 to 6 in the year under report.

Offences and punishments.—The total number of offences committed by convicts during the year was 6,836 against 6,715 in 1926. The increase is due chiefly to rise in the jail population. Compared with the previous year there was an appreciable increase in the number of offences relating to work, while

those relating to prohibited articles showed a considerable decline. The ratio of punishments to the daily average population was 109.12 against 122.34 in the previous year.

Statistics of Sickness and Mortality.—The health of the prisoners during the year under report showed a very marked improvement as compared with the health record of the preceding years since the creation of the province in 1912. The daily average number of prisoners of all classes was 7,503.24, or 957.61 more than the figure of the previous year, while the total number of admissions to hospital, the sick rate per mille of average strength, and the mortality rate, were the lowest in the health records of the Bihar and Orissa Jail Department. There was a further fall in the ratio per mille of average strength of admissions to hospital and of daily average sick, the figures being 447.6 and 17.9, respectively, against 613.4 and 24.3 in 1926. The total number of deaths was 78 against 72 in the previous year. This small increase, however, did not adversely affect the death-rate per mille as, owing to the rise in the daily average population, the mortality-rate was actually less than that of the previous year, the figure being 10.3 against 10.9.

A noteworthy feature is the reduction in the number of admissions for bowel diseases, viz., dysentery and diarrhoea, which were reduced by 54 per cent. as compared with the preceding year. This was brought about by the early recognition and treatment of irregularity of bowel action and by careful regulation of diet and hygienic treatment of the general body of prisoners according to season, and bears testimony to the keen interest taken by the Superintendents and medical staff of the jails in the welfare of the prisoners.

The largest number of deaths occurred in the central jails at Gaya, Bhagalpur and Buxar and in the district jails at Purnea and Sambalpur, which were responsible for 13, 11, 8, 9 and 6 deaths, respectively.

Cholera.—There were 4 cases with one death from this cause against one case only in the previous year. Three cases occurred in subsidiary jails and one in the Sambalpur jail, which proved fatal. These sporadic cases are usually due to infections outside the jail or to flies, but prompt measures were taken to arrest the disease and no further cases occurred.

Dysentery.—The year under report showed a marked fall in the incidence of and deaths from this disease, which has caused so much anxiety in the past to the medical management of the jails of this province. There were 176 cases with 3 deaths against 379 cases with 9 deaths in 1926. The largest number of cases occurred at Muzaffarpur jail, viz., 29. The central jails at Buxar and Gaya showed a remarkable fall in the number of cases, there being only 7 and 17 admissions to hospital against 45 and 153, respectively, in 1926. The deaths occurred in the district jails—at Motihari and Sambalpur and at the subsidiary jail at Dhanbad. The reduction in the number of admissions and deaths during the year under report is most encouraging and is to be attributed to the careful and systematic examination of the stools of all newly admitted prisoners and to the thorough supervision exercised over feeding and sanitary arrangements. The fall in the incidence of this disease and more particularly in the death-rate, since the introduction of systematic anti-hookworm examination and treatment, is most instructive. The attempts to provide a more balanced and scientific dietary have also materially helped.

Ankylostomiasis.—The stool examination of all the newly admitted prisoners was carried on throughout the year and ova were detected in 7.140 or 51.17 per cent. of the cases examined during the year.

This figure is, however, of the nature of an average, as infection is known to vary in different localities, some being much more heavily infected than others.

The general health of the prisoners improved remarkably owing to the introduction of this system of examination and the decrease in the number of cases of bowel complaints is largely the result of these precautions.

Leprosy.—All the leper prisoners of the province

are concentrated in the district jail at Muzaffarpur for segregation and treatment. The daily average number of lepers during the year was 28.97 against 21.01 in 1926.

Malaria.—The number of admissions fell from 789 to 533 and deaths from 7 to 3. The decline in the incidence of the disease was due mainly to the fall in the number of cases at Buxar and Gaya. The number of cases in these jails was 125 and 20 against 206 and 186, respectively, in the previous year. Of the 3 deaths, one occurred at each of the central jails at Buxar and Gaya and one at the district jail at Purnea.

In most of the jails prophylactic treatment with cinchona febrifuge in place of quinine was continued during the year and the results were reported to be good.

Pulmonary Tuberculosis.—The number of cases and deaths from this disease fell from 52 and 18 in 1926 to 43 and 10 in the year under report. The Muzaffarpur jail recorded the largest number of admissions to hospital and deaths from this disease, viz., 7 and 3, respectively. The central jails at Buxar and Gaya and the district jails at Chapra and Purulia returned 4 cases each.

Anæmia and Debility.—There was a remarkable decline in the number of cases from this cause during the year, the figure being 4 against 20 in 1926. There was only one death against the same number in 1926. Here, again, anti-hookworm treatment enters largely into the improvement attained.

Influenza.—Two hundred and ninety cases of this disease occurred with 2 deaths against 245 cases and 1 death in the previous year. The central jails at Bhagalpur and Gaya and the district jail at Bankipur were responsible for the largest number of cases, viz., 114, 107 and 48, respectively. The deaths occurred at the Gaya central jail. The epidemics were again of a mild type.

Filariasis.—There were 2 cases of filarial fever as compared with 15 cases in 1926. The percentage of filarial infection among the prisoners of the Puri jail was 23. Much good work is being done in this jail in connection with the filaria laboratory of the adjoining civil hospital where research is being carried on and prisoners are given the benefit of the most up-to-date treatment.

Pneumonia.—The number of admissions to hospital and deaths fell from 48 and 7 in 1926 to 39 and 6 in the year under report.

Other Respiratory Diseases.—The number of cases and deaths from this cause increased from 157 and 2 to 202 and 4, respectively. The increase was due to the larger number of admissions from this cause in the central jail at Buxar and the district jail at Chapra which were responsible for 71 and 11 cases against 23 and 1. Two deaths occurred at Chapra jail and one at each of the central jails at Buxar and Bhagalpur. Many of these cases no doubt occur in connection with influenzal infections of mild and irregular type.

Diarrhoea.—The incidence of this disease fell by 54 per cent. as compared with the previous year, the number of cases being 227 against 491 in 1926. There were 2 deaths against one in 1926.

Abscesses and Boils, Etc.—The total number of cases from these causes was 183 against 236 in 1926. There was no death.

Accommodation.—The total accommodation available on the 31st December, 1927, in the jails and subsidiary jails of this province was 11,036 against 10,796 or an increase of 240 as compared with the previous year. The accommodation at the central jails at Hazaribagh and Bhagalpur increased by 205 and 35, respectively, due mainly to the construction of a double storied barrack in the former jail and to the construction of a ward in the latter for tuberculous prisoners.

Prisoners' Weight.—Of the 14,809 convicts released during the year from central and district jails, 57.17 per cent. gained weight, 16.09 per cent. lost weight and 26.74 per cent. neither gained nor lost weight, the figures of the previous year being 57.69, 14.89 and 27.42, respectively.

ADMINISTRATION REPORT ON THE JAILS OF BIHAR AND ORISSA, FOR THE YEAR 1926. BY LIEUT.-COL. I. M. MACRAE, O.B.E., M.B., I.M.S., INSPECTOR-GENERAL OF PRISONS, B. & O. PATNA, SUPDT., GOVT. PRINTING, B. & O. PRICE Rs. 2.

The total accommodation available on the last day of the year in the jails and subsidiary jails of the province was 10,796 against 10,865 in 1925. The decrease is due to the dismantlement of a dilapidated ward in the Buxar central jail. During the year the jail at Purnea, which was reduced to a subsidiary status in 1922, was restored to its former status of a district jail, thereby increasing the number of central and district jails from 16 to 17 and reducing the number of subsidiary jails from 51 to 50.

The daily average number of prisoners of all classes and of convicts rose from 6,227 and 5,298, respectively, in the previous year to 6,545 and 5,488 in the year under report.

The total number of youthful offenders and juveniles up to 20 years of age admitted during the year was 742 against 811 in the previous year. Of these, 56 juveniles, namely 49 boys and 7 girls, were under 15 years of age as compared with 30 boys and 3 girls in 1925. Fourteen of these boys were sent to the reformatory school at Hazaribagh and the rest, as well as those between 15 to 20 years of age, were either detained in the jails of the districts in which they were convicted or transferred to the juvenile jail at Monghyr, to the central jail at Bhagalpur, and to the district jail at Bankipur.

Four hundred and thirty boys were dealt with in the Monghyr juvenile jail during the year under report and the daily average population was 141 against 132 in the previous year. The status of the school was raised to that of an upper primary school during the year and an additional teacher sanctioned for the Hindi section of the school. Night school continued during the whole of the year and religious instruction was imparted to the boys twice a week by ministers appointed for the purpose.

Unfortunately the Juvenile Prisoners' Aid Society at Monghyr could not do any useful work during the year owing to lack of funds. A special appeal circulated throughout the province for funds and support failed to elicit any satisfactory response, and it is feared that the institution—the only one of its kind in the province—will have to close down for want of public support.

It is gratifying to note that there has been a slight improvement in the number of prisoners sentenced to short terms of imprisonment. The percentage of prisoners receiving sentences of three months and under is 54.87 against 57.79 in the previous year.

Sentences of simple imprisonment decreased from 7.86 in 1925 to 5.51 in the year under report. This is due to the amendment of the Code of Criminal Procedure restoring the power of magistrates to award either simple or rigorous imprisonment under section 123(6) of the Code.

In view of the satisfactory results attained during the experimental period by the star class system of classification of prisoners introduced in the Hazaribagh central jail, with effect from the 25th December, 1924, Government have made the system permanent at that jail and have sanctioned an allowance of Rs. 10 a month to an assistant jailer to teach the star prisoners reading and writing, and of Rs. 2 a month to a head warder to train them in physical drill.

Sixteen escapes, seven among convicts and nine among undertrials, took place during the year against 13 in the year before. Of these, five convicts and six undertrials were re-captured before the year closed. In all cases the warders responsible for the escapes were suitably dealt with, either judicially or departmentally.

There was an appreciable increase both in the total number of jail offences and punishments and of punishments inflicted on warders and head-warders as compared with the previous year, the figures being 6,715

and 1,608 respectively, against 5,519 and 1,207 in 1925, the central jail at Buxar being responsible for an increase in jail offences from 884 in 1925 to 1,575 in the year under report. The number of corporal punishments fell from 9 in 1925 to 4 in the year under report.

The working of the manufactory department was more satisfactory than in the previous year. The total cash earnings and cash earnings per head increased from Rs. 60,928-8 and Rs. 12-3 respectively in 1925 to Rs. 1,06,813-14 and Rs. 20-3 in the year under report. The total net earnings and net earnings per head, however, decreased, the figures being Rs. 1,41,343-7 and Rs. 26-12 against Rs. 1,50,211-3 and Rs. 30-1 respectively in the preceding year.

The Buxar central jail showed a fall both in cash earnings and net earnings although the daily average number of prisoners employed in the factory was higher than in the preceding year. The manufactory department at Bhagalpur, however, continued to show satisfactory results. There were increases in both cash earnings and net earnings, the figures being Rs. 29,609-8 and Rs. 20,917-12 against cash deficit of Rs. 1,07,914-8 and Rs. 16,309-14 respectively in 1925.

On the whole the improvement shown last year in the health record of the prison population has been maintained. The sick-rate per mille of average strength, 24.3, the number of deaths, 72, and the death-rate per mille, 10.9, were almost the same as in the previous year. The Bhagalpur jail, formerly so unhealthy, returned the lowest death-rate; whilst the district jail at Muzaffarpur was responsible for the highest death-rate, being 43.8 against 16.9 in 1925; the district jail at Cuttack also showed a bad health record in the year under report.

There has been a slight increase in the incidence of and mortality from dysentery during the year, there being 379 cases and 9 deaths against 322 and 5 respectively in 1925. The central jail at Gaya is chiefly responsible for the increase.

In accordance with the recommendation of the Indian Jails Committee several further changes were made during the year. An additional cotton *kurtia* is now issued to all prisoners sentenced to rigorous imprisonment, giving thereby to each of them two complete suits of cotton clothing. The scales of gratuity prescribed for convict night-watchmen and convict overseers have been raised from Re. 0-1-6 and Re. 0-4-0 a month to Re. 0-4-0 and Re. 0-8-0 respectively, as an experimental measure.

Correspondence.

DIPHTHERIA IN INDIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Four years ago I came across a case of diphtheria in my own house in a child of about two and a half years. He was a bottle-fed baby. At first I took it to be a case of croup and I treated him accordingly. I had already dismissed diphtheria from my mind for I was sure that diphtheria was uncommon in this Chhattisgarh tract of the Central Provinces.

The toxæmia, the rattling in the throat and the difficult breathing went on increasing and the child remained in this state for two days. While cleaning his tongue one morning it was noticed that the piece of muslin was stained with blood. I was present. On examining the throat I found it covered with a whitish, pale, slough-like covering. I had seen a diphtheria throat before and the text-book reading—"It bleeds readily on detaching"—came as a flash to my mind and I took a smear at once. I showed the slide to my officer, Dr. A. C. Sen, who was not definite but said at the time that the organisms might simulate diphtheroids at least. There was, however, anti-diphtheria serum in the Sarangarh State Hospital and I inoculated the baby at once. The croup-like distress disappeared

those relating to prohibited articles showed a considerable decline. The ratio of punishments to the daily average population was 109.12 against 122.34 in the previous year.

Statistics of Sickness and Mortality.—The health of the prisoners during the year under report showed a very marked improvement as compared with the health record of the preceding years since the creation of the province in 1912. The daily average number of prisoners of all classes was 7,503.24, or 957.61 more than the figure of the previous year, while the total number of admissions to hospital, the sick rate per mille of average strength, and the mortality rate, were the lowest in the health records of the Bihar and Orissa Jail Department. There was a further fall in the ratio per mille of average strength of admissions to hospital and of daily average sick, the figures being 447.6 and 17.9, respectively, against 613.4 and 24.3 in 1926. The total number of deaths was 78 against 72 in the previous year. This small increase, however, did not adversely affect the death-rate per mille as, owing to the rise in the daily average population, the mortality-rate was actually less than that of the previous year, the figure being 10.3 against 10.9.

A noteworthy feature is the reduction in the number of admissions for bowel diseases, viz., dysentery and diarrhoea, which were reduced by 54 per cent. as compared with the preceding year. This was brought about by the early recognition and treatment of irregularity of bowel action and by careful regulation of diet and hygienic treatment of the general body of prisoners according to season, and bears testimony to the keen interest taken by the Superintendents and medical staff of the jails in the welfare of the prisoners.

The largest number of deaths occurred in the central jails at Gaya, Bhagalpur and Buxar and in the district jails at Purnea and Sambalpur, which were responsible for 13, 11, 8, 9 and 6 deaths, respectively.

Cholera.—There were 4 cases with one death from this cause against one case only in the previous year. Three cases occurred in subsidiary jails and one in the Sambalpur jail, which proved fatal. These sporadic cases are usually due to infections outside the jail or to flies, but prompt measures were taken to arrest the disease and no further cases occurred.

Dysentery.—The year under report showed a marked fall in the incidence of and deaths from this disease, which has caused so much anxiety in the past to the medical management of the jails of this province. There were 176 cases with 3 deaths against 379 cases with 9 deaths in 1926. The largest number of cases occurred at Muzaffarpur jail, viz., 29. The central jails at Buxar and Gaya showed them in the following condition.

He was lying on his back with both legs extended, he was catching the abdominal skin of the lumbar region on the left side with his left hand; he was perspiring and his breathing was hurried. He complained of pain in the left lumbar region where he was holding with his left hand. He noticed the pain first in the previous night but now it was more severe. I could detect no other abnormalities.

At first sight I thought it to be a case of intestinal colic, so I prescribed one ounce of brandy with 10 minims of tincture of opium and a hot water bottle to the abdomen. A few minutes later it seems he felt better and he was fed with a little rice, with my consultation; soon after this he took a serious turn. At about 12-30 noon I was called again to see the patient as he was in a precarious condition. This time he was unconscious, teeth were clenched, eyes were closed, and the whole body was still. So I dashed cold water on his face two or three times, after which he came to his senses, but he had cramps in his hands and legs. I gave him one hypodermic injection of digitalin gr. 1/100 and strychnine gr. 1/100 and prescribed the following mixture.

Pot. bromide	gr. x.
Chloral hydrate.	gr. v.
Tinct. hyoscy.	5ss.
Aqua m. ad	5i.

are concentrated in the district jail at Muzaffarpur for segregation and treatment. The daily average number of lepers during the year was 28.97 against 21.01 in 1926.

Malaria.—The number of admissions fell from 789 to 533 and deaths from 7 to 3. The decline in the incidence of the disease was due mainly to the fall in the number of cases at Buxar and Gaya. The number of cases in these jails was 125 and 20 against 206 and 186, respectively, in the previous year. Of the 3 deaths, one occurred at each of the central jails at Buxar and Gaya and one at the district jail at Purnea.

In most of the jails prophylactic treatment with cinchona febrifuge in place of quinine was continued during the year and the results were reported to be good.

Pulmonary Tuberculosis.—The number of cases and deaths from this disease fell from 52 and 18 in 1926 to 43 and 10 in the year under report. The Muzaffarpur jail recorded the largest number of admissions to hospital and deaths from this disease, viz., 7 and 3, respectively. The central jails at Buxar and Gaya and the district jails at Chapra and Purulia returned 4 cases each.

Anemia and Debility.—There was a remarkable decline in the number of cases from this cause during the year, the figure being 4 against 20 in 1926. There was only one death against the same number in 1926. Here, again, anti-hookworm treatment enters largely into the improvement attained.

Influenza.—Two hundred and ninety cases of this disease occurred with 2 deaths against 245 cases and 1 death in the previous year. The central jails at Bhagalpur and Gaya and the district jail at Bankipur were responsible for the largest number of cases, viz., 114, 107 and 48, respectively. The deaths occurred at the Gaya central jail. The epidemics were again of a mild type.

Filaria.—There were 2 cases of filarial fever as compared with 15 cases in 1926. The percentage of filarial infection among the prisoners of the Puri jail was 23. Much good work is being done in this jail in connection with the filaria laboratory of the adjoining civil hospital where research is being carried on and prisoners are given the benefit of the most up-to-date treatment.

Pneumonia.—The number of admissions to hospital and deaths fell from 48 and 7 in 1926 to 39 and 6 in the year under report.

Other Respiratory Diseases.—The number of cases and deaths from this cause increased from 157 and 2 to 202 and 4, respectively. The increase was due to the

Major H. G. Alexander, F.R.C.S., I.M.S., held charge of the Civil Surgeoncy of Darjeeling, during the absence, on leave, of Major Bomford, I.M.S., from the 18th September to the 3rd October 1928.

Major S. A. McSwiney, I.M.S., Officiating Second Professor of Midwifery, Medical College, Calcutta, was appointed to act as Professor of Midwifery of the institution, in addition to his own duties, from the 12th to 30th October 1928.

LEAVE.

Lieutenant-Colonel J. K. S. Fleming, O.B.E., I.M.S., Deputy Director-General, Indian Medical Service, is granted an extension of three days' leave in continuation of the leave granted to him previously.

Lieutenant-Colonel V. B. Green-Armytage, M.D., F.R.C.P., I.M.S., Officiating Professor of Midwifery, Medical College, Calcutta, and Obstetric Physician and Surgeon, Medical College Hospital, is allowed leave on average pay for six months, with effect from the 12th October 1928.

Lieutenant-Colonel C. H. Barber, D.S.O., I.M.S., Civil Surgeon, Naini Tal, is granted leave on average pay for four months, with effect from 1st December 1928, or date of availing.

Major G. Covell, M.D., I.M.S., an Officer of the Medical Research Department, is granted leave on average pay for eight months combined with study leave for three months

BLOOD tests in relation to blood transfusion interest both the clinician and the serologist. To their serologist they open up methods of wide technical education, and for the clinician they prepare the way for a successful transfusion. The sub-jectory side, though brief references to the

PROMOTIONS.

Captains to be Majors.

John Smart Galvin, M.B., I.M.S. Dated 5th September 1928.

G. A. Hildreth, M.B. Dated 11th December 1928.

The promotion to his present rank of Major J. C. John, O.B.E., M.B., I.M.S. is ante-dated from the 27th July 1924 to the 27th January 1924.

Lieutenants to be Captains.

W. J. A. Coldstream. Dated 1st October 1928.

Lieutenant J. Quigley to be Captain (provisional). 1st September 1927.

RETIREMENTS.

Lieutenant-Colonel P. M. Rennie. 23rd August 1928.

Lieutenant-Colonel S. A. Razzak. 1st November 1928.

Lieutenant-Colonel J. B. Christian, I.M.S. 27th June 1928.

NOTES.

CENTENARY OF KING'S COLLEGE.

Work of the Medical Faculty.

ONE of the first Faculties to be established was that of medicine; not long after its establishment, in 1839, the College initiated King's College Hospital in Lincoln's Inn Fields, and from the very beginning medical science has flourished within its walls. Among those responsible for the Faculty in the early days were such men as Herbert Mayo, Richard Partridge, and John Curnow, the anatomists, and Bentley Todd, William Bowman, Lionel Beale, and William Rutherford, the physiologists. Others on its staff have been David Ferrier, Peter Thompson, T. J. Brodie, Alfred Garrod, and Gerald Yeo, whilst it will always be remembered with pride that the College was responsible for bringing Lister back to London in the face of considerable opposition. We need only recall the names of Prof. Arthur Robinson, Prof. David Waterston, Prof. J. E. S. Frazer, Prof. E. Barclay-Smith, Prof. W. E. Dixon, Prof. W. D. Halliburton, and Sir Charles Martin as representative of the many distinguished men who have worked at the College in later years to the advantage of medicine.

Before the war the number of students in the Medical Faculty was about 170, but last year it had risen to 211. The College has the advantage of co-operating not only with King's College Hospital at Denmark-hill, but also with St. George's, Charing Cross, and Westminster Hospitals, from which students come for pre-clinical work. Those who receive their medical education at the College have the considerable advantage

With this brief clinical note we may now pass to the tests which are applied to the blood of the recipient and proposed donor to determine their compatibility or otherwise.

A study of the well-known table of Moss at once indicates that only by the use of group II and group III stock sera can we assign any given unknown blood to its correct group, for this is the only combination of two from the four available sera which will yield a different pair of agglutination reactions with each blood group. It is evident that the four possible reactions which may occur are as follows:—Both may be positive, in which case the unknown blood is group I. Both may be negative, in which case the unknown blood is group IV. If group II serum yields a positive and group III a negative result, then the unknown blood belongs to group III. If group III serum yields a positive and group II a negative result, then the unknown blood belongs to group II. The iso-agglutinins, upon which these reactions are dependent, are part of the chemical make-up of the individual, and remain unchanged throughout life. They are ordinarily of quite low titre, usually about 1 to 30. This fact will be seen later to have important applications. These iso-agglutinin sera are fortunately not very susceptible to temperature, and will even act power-

ful. This book should be of considerable interest to old King's College students of whom there must be many in India.

INTERNATIONAL MEDICAL POST-GRADUATE COURSES IN BERLIN.

International Medical Post-graduate Courses in Berlin are arranged with the help of the medical faculty of the University by the Lecturers' Association for medical continuation courses and the Kaiserin Friedrich-Haus. Part of the courses take place permanently, part only in March/April, 1929.

I. Permanent Courses.

(a) Course during 2 to 4 weeks.

(b) Courses as guest-assistants in clinics, hospitals and laboratories during 2 to 3 months and longer for gentlemen desiring to do practical work under systematic supervision.

II. Courses in March/April, 1929.

(a) General course: "Progress in the realm of Medicine with special regard to diseases of the heart" (from 4th—16th March) with the co-operation of the following gentlemen: v. Bergmann, Dresel, F. Klemperer, Munk, Rosin, V. Schilling, Schlayer, Straub. Fee RM 80.

(b) Special course in urology (from 18th—23rd March) with the co-operation of the following gentlemen: Bätzner, Casper, E. Joseph, v. Lichtenberg, Ringleb, Rumpel. Fee RM 75.

(c) Special course in surgery on the theme: "A week on breast and stomach surgery" (from 18th March—13th April) with the co-operation of the following gentlemen: Bätzner, Bier, Borchardt, Katzenstein, Kisch, Müsam, Sauerbruch, Unger. Fee RM 75.

(d) Special course in Röntgenology, taking into particular consideration its application in surgery (from 14th—21st April) with the co-operation of the following gentlemen: Chaoul, Max Cohn, Cramer, Frik, Hintze, Lazarus, Levy-Dorn, Munk, Rumpel. Fee RM 100.

(e) Single courses on all special fields of medical science including practical work.

The courses are held in German, but numerous professors are able to lecture in the English, French and Spanish languages.

The information bureau of the Kaiserin Friedrich-Haus für das ärztliche Fortbildungswesen, Berlin NW 6, Luisenplatz 2-4 is instrumental in procuring suitable lodgings, gives information as to cost of stay, arranges the attendance in clinics at operations, etc., and, upon request, sends detailed syllabuses.

[Note.—RM = Reichmark: 1½ Reichmark = 1 rupee (roughly).—ED., I. M. G.]

SMALARINA CREMONESE.

THERE are numerous very encouraging reports from Italy regarding the value of Smalarina Cremonese in the treatment of malaria. The reports have been so favourable that the Premier, Signor Benito Mussolini, has decided to apply this new form of treatment in all the malaria-stricken provinces in Italy.

This drug has not yet had an extensive trial in India. A trial in a small number of cases is quoted in the number of the Gazette.

ESTIMATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In a recent paper in the *Indian Medical Gazette* (November 1928, p. 624), I have described a bed-side blood-sugar method using as little as 1/50th of a c.c. of blood.

Using a colorimeter,—but otherwise the technique being the same,—I find the method to be quite satisfactory even for the laboratory. Indeed I consider it to be very suitable both for clinical and experimental work, specially when the blood of small animals is to be examined repeatedly for blood-sugar.

~~The loss of 2 or 4 drams of the solution which~~

NOTES ON BURROUGHS WELLCOME & CO.'S EXHIBIT AT THE BRITISH MEDICAL ASSOCIATION MEETING AT CARDIFF, JULY 1928.

YEAR after year the tastefully arranged and distinctive Burroughs Wellcome & Co. stand provides a unique record of the current year's medical, pharmacological, bacteriological, chemical and pharmaceutical progress. A prominent position was given to Ephedrine which has now proved its right to be included amongst drugs of known value. In addition to its use in asthma and hay-fever, this alkaloid has been found efficient as an analgesic in leprosy. As "Tabloid" Ephedrine may be taken by the mouth, it presents some advantages over adrenalin which must be injected and with which it is frequently compared.

A notable product was seen in "Wellcome" Liver Extract which is an active, selected fraction of an extract derived from fresh liver, prepared by a process which has been tested and found efficient by the Medical Research Council. The product is specific in pernicious anaemia. It is issued in tubes, each of which is derived from half-a-pound of fresh liver.

The value of "Moogrol," a mixture of esters of the chaulmoogric acids, in leprosy has been definitely established as a result of careful clinical trials. A more recent development, however, was shown in "Alepol" which consists of the sodium salts of the less irritating, lower melting-point fatty acids of hydnocarpus oil. By means of this product treatment can be considerably improved. "Avenyl," which is a short title for 2-myristoxy-mercuri-3-hydroxybenzaldehyde, is used in cases of leprosy complicated with syphilis. It may be recalled that in this condition ordinary arsenical products used in the treatment of syphilis are apt to intensify the leprotic condition.

A representative display of standard Burroughs Wellcome & Co. products added to the general attractiveness of the exhibition. It is of interest to note that "Wellcome" Sera, Vaccines, and Tuberculin are Britishmade at the Wellcome Physiological Research Laboratories and that no physician need depend on foreign sources for a supply of any of these important adjuncts to modern practice.

FRANK ROSS & CO., LTD.

It will be of some interest to our Calcutta readers to hear that the above well-known firm of dispensing chemists have reopened their Park Street branch at No. 37, Park Mansions.

THACKER, SPINK & CO., LTD.

The firm of Thacker, Spink and Co. is referred to as pioneers in the publishing trade, having been established in 1819. They early acquired a world-wide reputation for the publication of technical, and legal works, specially relating to to-day continue to issue many works of merit, as may be seen from the pages of my catalogue of publications, just issued. The publication, *Singh, L.A.I., L.C.P.S.,* is a speciality of the firm, and contains many books which are in the hands of authorities, some having been in circulation for many years.

"THE ACTINIC PRACTITIONER AND ELECTROTHERAPIST."

THE first number of "The Actinic Practitioner and Electrotherapist," a professional journal for practitioners and those engaged in the administration of actinotherapy, medical radiology and electricity, has just come to hand. The purpose of this journal may best be defined by quoting from its editorial columns:—

"Under medical direction and supervision it will seek to deal, month by month, with the progress of these and allied matters, to give practical help to its readers in their technical and other difficulties, and, in short to provide a professional journal which will be valuable not only to those interested in theory, but to every person legitimately practising these new branches of medical treatment."

The first number contains authoritative articles on such subjects as:—The Position of Electricity in Medical Practice, Elements of Practical Actinotherapy—The Choice of Lamps, Starting and Equipping a Small Sun-light Clinic, and Simple Physics of Actinotherapy.

It is intended to issue the journal monthly—the subscription rate for India is seven shillings per annum, post paid. Further information is obtainable from:—The Manager, The Actinic Practitioner and Electrotherapist, 139, High Holborn, London, W. C. 1.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints gratis, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

BLOOD TESTS IN RELATION TO BLOOD TRANSFUSION.*

By R. B. LLOYD, M.A., M.B., B.Ch.,
LIEUTENANT-COLONEL, I.M.S.,

Imperial Serologist and Professor of Serology,
Calcutta School of Tropical Medicine.

It is of course a truism to say that blood transfusion, after many vicissitudes in its history, is now one of the most powerful means at our disposal in dealing with emergencies of many kinds. There are conditions in which it is hardly worth while wasting valuable time in the application of other modes of treatment. There is nothing more dramatic in the whole of medicine than to witness a technically correct blood transfusion with a donor of the correct group given to a patient who is in *extremis* from grave hæmorrhage, and to see the extraordinary rapidity of the return to a condition in which the patient is out of danger.

The indications for blood transfusion fall into four well-defined groups. (1) The acute anæmia caused by sudden and grave hæmorrhage, chiefly illustrated by war casualties, post-partum hæmorrhage and ruptured ectopic gestation. Blood transfusion for these conditions is now invariably employed. (2) Anæmia of gradual onset in which a single transfusion is often of great value to assist a patient in poor condition to withstand the shock of a surgical operation. We may extend this to include the case of patients who are gravely ill from such diseases as kala-azar. Blood transfusion as an auxiliary treatment may enable such patients to react successfully to special drugs which have some degree of toxicity, such as the antimony compounds. Transfusion in this class of case must be used with circumspection as the post-transfusion reactions may be severe. (3) A third group comprises the hæmorrhagic diseases in which transfusion is used partly to replace blood lost, and partly to terminate the hæmorrhage. The best examples of this class are hæmophilia and *melæna neonatorum*. (4) In general toxæmias of many kinds a blood transfusion may in some cases be a valuable mode of treatment, e.g., very good results have been obtained in sprue. The employment of blood transfusion in the treatment of this class of case is not altogether devoid of risk if the anæmia be extreme.

With this brief clinical note we may now pass to the tests which are applied to the blood of the recipient and proposed donor to determine their compatibility or otherwise.

A study of the well-known table of Moss at once indicates that only by the use of group II and group III stock sera can we assign any given unknown blood to its correct group, for this is the only combination of two from the four available sera which will yield a different pair of agglutination reactions with each blood group. It is evident that the four possible reactions which may occur are as follows:—Both may be positive, in which case the unknown blood is group I. Both may be negative, in which case the unknown blood is group IV. If group II serum yields a positive and group III a negative result, then the unknown blood belongs to group III. If group III serum yields a positive and group II a negative result, then the unknown blood belongs to group II. The iso-agglutinins, upon which these reactions are dependent, are part of the chemical make-up of the individual, and remain unchanged throughout life. They are ordinarily of quite low titre, usually about 1 to 30. This fact will be seen later to have important applications. These iso-agglutinin sera are fortunately not very susceptible to temperature, and will even act powerfully when infected by heavy bacterial growth, though no one would trust reactions obtained with old sera.

Armed with these two stock sera of groups II and III it is next necessary to obtain suitable specimens of blood to group. The procedure which I have found extremely satisfactory is as follows:—The physician takes to the bedside of the patient two small test tubes. One of these contains 1 c.c. of normal saline, while the other is empty. He obtains 3 to 4 c.c. of blood by means of a syringe from a vein in the antecubital fossa. This is far better than pricking the finger, which painful operation usually produces insufficient blood in an exsanguinated patient. He then ejects the first 4 or 5 drops of blood into the normal saline and shakes up. This gives a suspension of the recipient's cells. The extensive dilution prevents coagulation, but if some hours are to elapse before the grouping tests are done, it is desirable to substitute 1.5 per cent. solution of sodium citrate for the saline. The remainder of the blood is ejected into the dry test tube and allowed to clot. If a donor is available at the hospital he then brings these two specimens from the recipient to the laboratory, and the same procedure is now carried out upon the donor, from whom a somewhat larger amount of blood—8 to 10 c.c.—is withdrawn in the usual way. After coagulation of the blood in the dry tubes, we now have four specimens. We first of all group the recipient's red blood cells by means of stock grouping sera. We then group the recipient's serum by means of cells of known groups which are at hand in the laboratory. These

* This paper was read at a meeting of the Calcutta branch of the British Medical Association on February 8th, 1929.

have been previously grouped against other known sera. The advantage of this technique is that in no instance will the report on the blood group be based on negative reactions alone. The group of a person as determined from his cells and from his serum is necessarily the same, except in very rare instances of abnormal types. Finally, as a control of the grouping sera used we test these against cells of known groups.

The same procedure is now carried out with the two specimens from the donor, and if they are of the same group as that of the recipient a direct match is made; i.e., the serum of the recipient is tested against the cells of the donor and *vice versa*. If both these reactions are negative for agglutination, the two persons are of the same group, and their bloods are compatible. It will be seen that we have now performed a very exact experiment. We have determined the groups of the recipient and the proposed donor, and we have confirmed the correctness of the grouping and the absence of abnormal types by a direct match. The above method is by far the best, and should always be employed where practicable. It involves access to a central laboratory with standard grouping sera. The full tests, apart from the Wassermann reaction on the donor, occupy perhaps 30 minutes in addition to the time required for the separation of the serum from the clot.

A second method is the employment of group IV professional donors. In sudden grave emergencies it is a great advantage to the clinician to have at hand known group IV donors whose blood may be transfused at a moment's notice without any reference to the laboratory. Hundreds of successful transfusions by means of universal donors have been performed, usually without any serious degree of reaction. Nevertheless, there are certain drawbacks to their use. It will be seen from Moss' table that while the cells of group IV are compatible with all other bloods, the serum of group IV is not. From the absence of untoward reactions after transfusion of blood from universal donors it may be inferred that the reactions of the serum of the donor are of little importance. The reason for this is not quite clear, though it would appear to be largely a question of dilution. In the normal transfusion of 500 c.c. into a patient whose total blood volume is approximately 5,000 c.c. the iso-agglutinins of the transferred serum are quickly diluted to 10 per cent. of their former titre. The titre of these agglutinin sera being usually low, the dilution is believed in large measure to prevent the occurrence of serious reactions which might on theoretical grounds be expected. It may be doubted whether this explanation is entirely adequate, and it has been suggested that the recipient can without disturbance absorb the disintegration products of his own cells which will result from the transfusion of an

incompatible serum, whereas he cannot without disturbance absorb the disintegration products of foreign cells. Should, however, the iso-agglutinin titre of a particular group IV serum be abnormally high, then it may still be extremely active even after dilution by the blood of the recipient. This factor is believed to explain the occasional occurrence of severe reaction after transfusion of blood from group IV donors. It will be seen, therefore, that there is a slight risk in the employment of a group IV universal donor who has never given blood before. If he has given blood before without bad results he is safer as a donor, though even here all his previous recipients may have been of group IV in which case no reaction would manifest itself.

If a universal donor is used at all, it is preferable always to employ a direct match as well. In this case, if the recipient is not group IV there will necessarily be some agglutination of the recipient's cells, though not of the donor's cells. The lower the red count of the recipient the more marked will the effect of the transfused serum be; so an important practical point is that in a patient whose red count is very low the use of a universal donor is not desirable, and a donor of the recipient's own group should be chosen. If we transfuse a patient with another blood of the same group we are injecting into him something very like his own blood. Universal donors often answer well enough in emergency transfusions for sudden hæmorrhage, but in old-standing anæmias where a transfusion always involves some degree of risk, universal donors should not be employed. Fortunately, in these cases there is always ample time to obtain a donor of the same group. As the use of blood transfusion has extended, there has been a tendency for the universal donor to drop out. I do not personally pass any donor as suitable unless he is of the same group as the recipient, and as I have on my register donors of all four groups, there is no object in using a universal donor.

Instances may occur where there are no facilities for grouping and no universal donors. The compatibility or otherwise of the bloods of the recipient and the proposed donor may then be ascertained by the direct matching process described above. This method will not identify the groups, but will show compatibility or otherwise. If absolute reliance is to be placed on this test, it is important to carry it out doubly; i.e., donor's cells against recipient's serum and *vice versa*. It is also desirable to repeat the test. Although this test is quite simple, it is, I think, doubtful whether physicians who have not had much laboratory experience would care to trust it absolutely where so much is at stake.

Although both grouping and direct matching should always be performed where possible, it is safer to depend on a direct match alone than on grouping alone, as direct matching has the

great advantage of showing up an abnormal type which grouping may fail to detect.

Coca has criticised the ordinary grouping tests on the ground that they are somewhat artificial, and that they are not quantitative. He has introduced an ingenious technique whereby the citrated bloods of the donor and recipient are mixed together on a slide in such proportions that the test carried out *in vitro* approximates very closely to the actual state of affairs produced by a transfusion. The dilutions are made by means of a hæmocytometer white cell counting pipette. Having washed this out with ten per cent. sodium citrate solution leaving the terminal 1/10 division filled with the citrate solution, the end of the finger of the recipient is pricked and a large drop of blood obtained. Into this the pipette is inserted and the blood drawn up to the 1 mark. It is then immediately blown out on to a slide, and gently stirred with the end of the pipette. This then is the undiluted blood of the recipient. For the purpose of the calculation the volume of the citrate is neglected. After washing out the pipette and again leaving the terminal 1/10 division filled with citrate, the finger of the donor is pricked and his blood is drawn up to the 1 mark. This is ejected as before on to a second slide. But in this case only nine-tenths is ejected, leaving the terminal 1/10 division filled with blood. Saline is now drawn up to the 1 mark. This second dilution is now blown out on to a third slide and well mixed with the end of the pipette. This provides a one-tenth dilution of the donor's blood, the volume of the citrate solution again being neglected. Now three divisions of the recipient's blood and three divisions of the one-tenth dilution of the donor's blood are drawn into the pipette and blown out on to a fourth slide and well mixed. A cover glass is then put on and the specimen watched for agglutination under the microscope. It will be seen that this technique mimics an actual transfusion of 500 c.c. into a patient who has the average blood volume of 5,000 c.c. It further has the advantage that one can often judge from the specimen whether, in the case of incompatibility, it is the donor's or the recipient's cells which are being agglutinated. While the method is a useful technical improvement in that it provides a quantitative direct match of whole bloods, I have not found the results quite so sharp as those yielded by grouping sera.

Coca subsequently modified his technique using one per cent. sodium citrate solution instead of ten per cent., and diluting in turn both the recipient's and donor's bloods with equal volumes of this weak citrate solution. He then mixes two divisions of the diluted donor's blood with ten divisions of the diluted recipient's blood. The mixture is then watched for agglutination under the microscope as before. With these dilutions the agglutination of an incompatible blood is much more easily seen.

I shall only refer very briefly to the communi-

cation of disease by blood transfusion. No guarantee can ever be given that the donor is free from all disease, though every effort is of course made to choose absolutely healthy persons. The most important disease is syphilis. Every donor should have his Wassermann reaction done. This is a great protection, but since there is no stage of syphilis, other than the secondary, which gives 100 per cent. of positive reactions, it follows that a negative Wassermann reaction is not absolute proof of the absence of syphilis. There are several instances in the literature of the communication of syphilis by transfusion. Malaria too is important. In one very successful transfusion here in Calcutta for which I performed the blood grouping tests, the only available donor of the correct group was a man who said he had been subject to fever but had not had any lately. He had never had syphilis, and as the patient, who was his sister, was dying from hæmorrhage, he was used without loss of time. Fifteen days later, when the patient had practically recovered, she had a rigor, and her blood was found to contain large numbers of benign tertian parasites. The fever was quickly controlled by quinine. I suppose that kala-azar could be transmitted by blood transfusion, though one has never heard of it. The question of the health of donors is a very important one. Common sense will suggest the rejection of all donors, who are feeling even slightly unwell, as they may be in the early stage of one of the specific infectious disorders, e.g., measles, which may thus be communicated to the recipient. In this connection there are advantages in using relations, if otherwise suitable, as blood donors, as the family may often know more of the donor's past history than he may care to admit to the doctor.

The near relations of the patient are not by any means necessarily of the same blood group. These groups are inherited according to the Mendelian law. I shall not refer to inheritance of blood groups now, but will only mention the special case of the blood groups of infants. The question is often asked as to whether human blood of any group may be transfused into an infant. This is important in the treatment of melæna neonatorum. It had been formerly stated that an infant had no blood group. The matter was fully investigated by Happ in America in 1920. He commenced by testing the reactions of the umbilical cord blood, and found that these seldom corresponded to the reactions of the adult. He found that the serum of an infant's blood will not usually give any reactions for the first month. The iso-agglutinins are usually present in the serum after one year, and are always present after two years. On the other hand, the reactions of the cells appear earlier, so that, determined from the blood cells, the infant frequently does exhibit selective reactions from birth. When the reaction of the serum is added to that of the cells, the definitive

the arteries show periarteritis, and marked infiltration of the submucous and muscular coats with mononuclear and eosinophile cell infiltration.

Discussion.—The ulcers are quite unlike the chronic gastric ulcer, which is generally single and has thickened edges. In this specimen, there are four large ulcers with irregular sloping in edges and flat shallow bases. Multiple large ulcers with irregular serpiginous border, firm smooth base and the presence of demonstrable thickening in the stomach wall at a considerable distance from the ulcer itself are very suggestive of syphilis (John A. Hartwell). Histologically, the points suggestive of a syphilitic origin are the marked perivascular round cell infiltration, the inflammation and thickening of the adventitia of the arterioles, the marked cellular infiltration of the submucous and muscular layers with a large proportion of plasma cells and mononuclears, with great thickening of the submucosa. We have not been able to demonstrate the presence of spirochaetae in the sections, but this is a very difficult problem and so far as we know, the only published case in which they were found was McNee's, and that only after a very large number of sections had been made. Although we have failed to demonstrate the spirochaetae in sections, we consider the features both naked eye and histological are highly suggestive of syphilis.

Clinically, this patient emphasises the value of routine examinations and the difficulty during operation of distinguishing gastric syphilis from a moderately early carcinoma.

We are indebted to Captain T. W. Barnard, M.S.R., F.R.P.S., Radiologist, Government General Hospital, Madras, for the photo of the stomach.

ON THE DETERMINATION OF AGE IN INDIANS, FROM A STUDY OF THE OSSIFICATION OF THE EPIPHYSES OF THE LONG BONES.

By S. M. HEPWORTH, M.B., D.M.R.E.,
MAJOR, I.M.S.

A METHOD of fixing the age of a girl or youth accurately and definitely is of use in medico-legal practice; whilst most methods are merely an expression of opinion at best, a method in which the condition of the epiphyses of the bones is actually seen on an *x*-ray plate is definite and scientific.

The determination of a standard for such a method is rendered difficult in India, because of the common lack of knowledge of the actual year of the birth, so the material for this study has been drawn from a few cases where the birth has been registered, and from the inmates of certain mission schools where the date of birth of the pupils is known with fair accuracy.

Those cases in which the epiphyses show a marked divergence in development from the average of those of a supposedly similar age, have been rejected, and the average age at which ossification occurs in the long bones is shown in the accompanying table.

From the examination of the joints of a large number of young Indians between the ages of 8 and 18 years, I have concluded that the age at which union of the epiphyses and the shafts of their long bones takes place, is $2\frac{1}{2}$ to 3 years earlier than the corresponding union in English and American peoples.

It appears that the epiphyses unite with the shafts somewhat earlier in girls than in boys.

Those bones have been chosen for this purpose of which a good radiogram can be taken with ease, and in making the examination the following points must be observed:—

(i) Pictures of the six main joints of the limbs, taken in a true antero-posterior direction, should be made in every case.

Marked divergences from the normal occur frequently in one or other bones of the body, but as a rule such divergences do not occur in more than one joint, and probably result from epiphyseal injury in childhood.

(ii) Very careful centering of the *x*-ray tube over the epiphyses is necessary, as it is quite easy to give an ununited epiphysis the appearance of union by directing the cone of rays obliquely.

(iii) Reliance should not be placed on those data in cases in which there is marked bony deformity in the body. In those cases in which no epiphysis has joined to its diaphysis, a very accurate estimate of the age can be made, when there are reliable standards for comparison, from the size and shape of the shadow of the epiphyses on an *x*-ray plate.

My thanks are due to Dr. H. M. Caldwell of the American Presbyterian Mission, Ferozepore, for help in obtaining the material for this study and for much of the radiography.

RADIOLOGY IN THE DIAGNOSIS OF CHRONIC APPENDICITIS.

By J. H. BARRETT.

CAPTAIN, I.M.S.,

Indian Military Hospital, Quetta.

IN examining the appendix area with the aid of the *x*-rays, the following questionnaire should be gone through.

(1) Is there a spasmodic hour-glass contraction of the stomach?

(2) Is the duodenal cap normal?

(3) Is the cæcum filled in normal time?

(4) Does the appendix fill in 24 hours, (a) partially, (b) completely, (c) completely, but with a backward kink, (d) in a segmented fashion?

(5) Does the appendix appear (a) with vacuoles, (b) with bulbous tip, (c) with concretions?

(6) Is the filled appendix (a) freely movable or adherent, (b) unduly long or unduly short, (c) unduly tender?

(7) Does the appendix empty with the cæcum?

(8) Is the filled cæcum tender on palpation or irritable on palpation (T. B.)?

(9) Does the cæcum empty with the rest of the large intestine, or is there an "island" residue at 24 or 48 hours?

(10) Can the coils of the cæcum and ascending and transverse colon be easily moved and separated, especially can the cæcum be displaced inwards?

(11) Has the appendix failed to fill in 24 hours and in addition is the cæcum tender?

(12) Is the large intestine, and especially the region of the hepatic flexure and proximal half of the transverse colon, (a) abnormally low, (b) kinked or adherent, (c) tender at any portion?

Deductions made from the X-ray findings.

The evaluation of each sign indicative of a possible appendicitis is not within the scope of this article. It will suffice to say that the deductions must be made on signs found and not on signs imagined. Neither should the radiologist lay too much stress on the history or on the clinical diagnosis. Where pain or tenderness is present over the filled cæcum he should get the patient (during screen examination) to put his index finger on the spot that hurts most. In simple low colon, it is usually over the hepatic flexure. In appendicitis it is usually over the root of the appendix. In intestinal colic it may be anywhere, though often over the splenic flexure.

Whilst it is not actually claimed that the *x*-ray will diagnose all cases of chronic appendicitis when present, I have formed the opinion that it will always help either directly or by a process of elimination, in clearing up a diagnosis if the condition really does affect the large bowel or the appendix.

The reasons why the method is not employed more than it is, are as follows:—(a) Certain cases are so blatant clinically that *x*-ray examination is unnecessary as the diagnosis is self-evident.

(b) In obscure cases with vague symptoms, the patient and his doctor prefer to wait and see.

(c) In cases examined by the *x*-rays the important signs may have been missed, and the unimportant ones given an important place when deductions are made. The result is a faulty opinion.

(d) The *x*-ray technique may be faulty. One bad film may render the *x*-ray evidence futile; repetitions are costly, and patients are not desirous of going through the whole procedure again.

It will thus be seen that the actual *x*-ray films must be almost perfect, the screen examinations conducted with extreme care and observation, and I might add that of course the proper time intervals must be observed, and as each examination, screen or film, is made the result must be entered up almost at once, so that errors due to tricks of memory may be excluded.

The most valuable signs of chronic appendicitis when present are:—

(1) Tenderness over a definite 48 hours barium "island" residue in the cæcum. (This points to a pathological condition in that area.)

(2) Appendix tender and kinked backwards.

(3) Tenderness over a definite appendix residue,—when the rest of the barium has left the cæcum.

(4) Imperfectly filled and vacuolated or segmented appendix, or an appendix with bulbous tip.

(5) Marked tenderness over the cæcal region and appendix, when there is still barium present and when it is not found possible to displace the coils of intestine towards the mid-line (in the lying position).

(6) An appendix partially filled which cannot be moved about on palpation in the lying position.

Other radiographic signs may be present and have a certain value and all should be carefully noted when forming an opinion.

Illustrative Cases.

Case No. 1.—Mrs. M. complained of chronic indigestion for 4 years. The tongue was nearly always coated and she was losing weight. She had occasionally vague pain over the right iliac fossa. She complained also of chronic constipation and lassitude.

Radiological findings.—An irregularly filled appendix showed. The appendix kinked and painful on pressure at 24 hours. Forty-eight hours delay in the cæcum. Cæcum adherent.

Operation.—A long, very thick, chronically inflamed appendix with a bulbous tip and bound down by adhesions.

Case No. 2.—M. W. Three years history of discomfort over the stomach and right side, foul tongue, headache, malaise, and constipation. Lack of energy. Clinically there was no tenderness over the appendix.

Radiological findings.—Spasmodic hour-glass contraction of the stomach relieved by belladonna. Stomach normal otherwise. The filled cæcum was tender and there was a residuum in the appendix at 48 hours and after all the barium had left the cæcum. Appendix only partly filled and not segmented.

Operation.—Short appendix, adherent, thick, and chronically inflamed.

Case No. 3.—P. S. T. History of periodic violently acute attacks of pain in the stomach followed by vomiting, faintness, and diarrhoea. The attacks came on quite suddenly and never within an hour after taking food. Had six violent attacks in the past 4 months. He was absolutely doubled up with pain. Clinically there was practically nothing to be noted. Between the attacks he was quite normal in every way.

Radiological findings.—Stomach high and hypertonic, duodenal cap not seen. Stomach otherwise normal. Food at the splenic flexure in 3 hours (rapid). Appendix partially filled at 24 hours. The appendix shadow was very markedly segmented, transverse, adherent and tender. Forty-eight hours delay in the appendix and cæcum. Cæcum adherent. The region of the hepatic flexure of the colon and the proximal 3 inches of the transverse colon was bound down to the cæcum and appendix area and could not be mobilized in the lying position. This was specially remarked in the x-ray report and adhesions were suggested.

Operation.—Long kinked and very adherent and chronically inflamed appendix. Three definite adhesion bands extending downwards from the hepatic flexure and transverse colon to the ilio-cæcal region (Lane's kink type).

Summary and Remarks.

The x-rays will often give the following information:—

- (a) Whether the appendix is diseased or not.
- (b) Its position.
- (c) Abnormally long or abnormally short.
- (d) Whether adhesions are present or not.
- (e) That the appendix is normal, and some other condition is present.

X-rays will often indicate to the surgeon—

- (a) Whether an operation is indicated or not indicated.
- (b) Whether his incision is going to be a local button-hole one over the appendix area or whether the larger and more central incision is necessary, i.e., in the case of complications or other conditions being present either associated with appendicitis, or due to some separate condition.
- (c) The presence of bowel kinks and adhesions, or of an abnormally low colon.

STUDIES IN THE TREATMENT OF FILARIASIS.

By R. N. CHOPRA, M.A., M.D. (Cantab.),
LIEUTENANT-COLONEL, I.M.S.,
Professor of Pharmacology,

and

S. SUNDAR RAO,

Darbhauga Research Scholar,
Calcutta School of Tropical Medicine and Hygiene.

FILARIAL infection is very prevalent in India, the endemic area is not only along the sea-coast, but extends for some hundreds of miles inland. Although a complete survey has not yet been carried out for the whole of India, the work done by one of the authors (S. S. R.) shows

that in 27 districts in Bengal the population is affected to the extent of 0.7 to 11.4 per cent.; in Behar, Orissa and Chota Nagpur the figures are much higher, going up to 27 per cent. Most of the sea-coast districts of Madras and Malabar are heavily infected and every year a large portion of the population of these areas is incapacitated as a result of this infection. The indigenous methods of treating filarial diseases, especially lymphangitis—which is the type which causes considerable suffering in endemic areas in India—are frequently very drastic. The application of severe counter-irritants, for example scalding by a hot iron, or the application of caustic substances to the enlarged glands or along the inflamed lymphatic trunk, is a fairly common method of treatment. Fasting is frequently enforced on the patient in addition to the above measures. For elephantoid growths, the application of leeches is the chief treatment. Applications of pastes made from the leaves, roots and resinous gums are among the standard methods of treatment in the indigenous medicine for elephantiasis. The formulæ of these are described in detail in many of the books on Ayurvedic medicine.

The modern treatment of filarial diseases is very largely surgical. The medicinal treatment of filarial infection and its manifestations has not been very successful. A perusal of the literature shows that little work has been systematically undertaken in this country to find out an effective treatment for this disease. The only treatment resorted to is symptomatic during the acute inflammatory attack and directed chiefly against the secondary infection. In chronic filarial lymphangitis, the abdominal glands are usually affected; the microfilariae do not get into the blood-stream and remain confined to the lymphatics. Many of the parasites subsequently introduced by the mosquito do not mature; those that mature lay embryos which work back, cause slight lymphatic obstruction and become secondarily infected. Progress of these cases is slow; only a small percentage, generally not more than 5 per cent., have microfilariae in the blood. The acute septic cases are secondary to streptococcal or staphylococcal infection in the body. The site of infection depends on whether the mature or the immature worm is the nucleus; a number of these may be present. In both these conditions an effective filaricidal drug would be of immense value. If the adult parasites could be killed as soon as the microfilariae were detected in the blood, the complications mentioned above could be avoided.

In India a few remedies have been tried from time to time with disappointing results. Rogers (1919-1920) first suggested the use of antimonyl tartrates in the treatment of filarial infections. He tried these compounds in the Medical College Hospital and in the Puri Jail and came to the conclusion that the drug on the whole gave encouraging results. Further work by the late

Dr. P. N. Das (1920), Civil Surgeon of Puri, showed that the drug had no marked effect on the microfilariæ, though they often produced beneficial effects on the pathological conditions and clinical symptoms. Various other drugs have also been tried from time to time. Methylene blue, urotropine, quinine, picric acid, various compounds of arsenic (both pentavalent and trivalent), colloidal metals, etc., have been tried, sometimes with apparently beneficial results; even the microfilariæ in the blood are said to have shown a marked reduction. We have noticed that the microfilariæ circulating in the

sites lie in the large lymphatic channels, or in the lymphatic glands, and consequently it is very difficult to get any drug to them in a sufficiently high concentration to kill them. It is well known that none of the drugs are absorbed by the lymphatic route in sufficiently large quantities to produce any effect and hence parasites remain unaffected. The case of schistosoma parasites, which lie in the abdominal blood vessels, is different, as antimony compounds injected into the blood-stream attain a sufficiently high concentration, though it may be only momentary, to have deleterious effects on these helminths.

GRAPH I.

Microfilaria count of persons receiving Bisnene injections.

blood show tremendous variations in numbers without any treatment. This is apparent from a study of graphs I and II. If one did not look at the microfilaria count in the control cases, one might be tempted to conclude that the drugs were producing some effect on the embryos.

The Filariasis Commission in British Guiana (1921) tried many preparations, but were equally unsuccessful. Both the adult parasites and microfilariæ appear to be very resistant to the action of medicinal agents whether given intravenously or by other routes. The adult para-

Another difficulty is that the patients in the majority of instances show little or no symptoms when the adult worms are active and the microfilariæ are circulating in the blood even in large numbers. It is said that only in about 5 per cent. of the cases are any symptoms manifested early; in most of the cases the discovery of microfilariæ is purely accidental. Their effects become evident later when lymphatic obstruction occurs, and are the result of the embolic obstruction, produced not only by the dead worms which obstruct the lymph flow, but

sometimes by the inflamed tissues becoming infected with pyogenic organisms and setting up suppuration in the part. As no information is available about the entry of drugs into the lymphatic channels, we decided to try the effect of various remedies given intravenously, or orally, to see if they penetrate there and produce any effects. We thought it might be possible that during the course of these trials we might hit on a drug which would penetrate to the worms in the lymphatics and destroy them. With this

the blood was carefully counted before the treatment was started, and counts were made at regular intervals during the course of treatment, and afterwards. By the decrease in the microfilarial count after injections or by their total disappearance it was to be inferred that the drug had some effect either on the adult worm or on the embryos. Where there was no decrease it was to be concluded that the drug had no effect. The patients under treatment had to be kept under observation for prolonged periods. The

GRAPH II.

Microfilaria Count of Control Cases.

object in view, a number of drugs (*vide* Table I) which are reputed to have a well-marked parasitocidal effect in the body were tested. Many of our patients were apparently healthy individuals with no clinical signs or symptoms of filariasis, but who had microfilariae in their peripheral blood. We thought that any drug producing baneful effects on the adult filaria would adversely affect their embryo producing power. The efficacy of the drug in these cases was, therefore, judged by the effect it produced on the number of microfilariae in the peripheral blood. Their number per cubic millimetre of

controls consisted of untreated persons with microfilariae in the blood who were kept under similar conditions; the microfilariae in their blood were estimated in the same way as in those under treatment.

Besides taking the microfilaria count of all the patients, both those under treatment as well as the controls, we carefully noted the reactions following the treatment. The urine was also examined for any abnormal constituents. These observations were carried out partly on selected inmates of the Presidency Jail, partly on in-patients of the Carmichael Hospital for Tropical

Diseases, and partly on out-patients attending the Calcutta School of Tropical Medicine and Hygiene. The following table gives a resumé of the drugs tried and the number of cases treated:—

This drug was tried on prisoners with filarial infection in the Presidency Jail who were otherwise healthy. A close study was possible in these cases and equal numbers of controls were kept under exactly similar conditions. A weekly

"Bisnene" (Union Drug Company).

Chemically this compound is the bismuth analogue of urea-stibamine, i.e., the urea compound of para-amino-phenyl bismic acid. Chopra and others (1928) found it suitable for intravenous injection. The initial dose given was 0.1 gm. in 3 c.c. distilled water intravenously, the maximum dose was 0.3 gm. in 10 c.c. of distilled water every week. The drug produced cough, tickling of the throat, swelling of the nasal mucous membranes, chill and sneezing, in the early stages of treatment; later on with larger doses hardly any reaction was produced.

count of the number of microfilariae circulating in the blood was done both in the patients undergoing injections and in the controls. The urine was examined for any abnormality before and during the course of treatment, and the reactions were carefully watched and noted. There was improvement in general health of all the patients under treatment, chiefly because they were kept under hospital conditions and were not doing hard physical work. The drug had no effect whatever on the embryos circulating in the blood. The details of the results obtained are given in the following table:—

TABLE II.

Bisnene.

Cases.	Age, Race and Sex.			Initial dose gm.	Total amount given.	Reaction.	REMARKS.
I	26	H.	M.	0.1	2.775 gms.	Cough, tickling of the throat blocking of the nose sneezing and chill during the early part of the treatment.	Vide Graphs I and II.
II	43	H.	M.	..	2.775 "

IV	42	H.	M.	..	2.25 "		
V	35	H.	M.	..	2.775 "		
VI	35	H.	M.	..	2.775 "		
VII	25	H.	M.	..	2.575 "		

"Antimosan" or Von Heyden 661.

This compound contains antimony in trivalent form. An aqueous solution is neutral in reaction and can be injected intravenously or intramuscularly without pain; it has also been given subcutaneously. The initial dose given was 2 c.c. of a 5 per cent. sterile solution intravenously; the maximum dose was 8 c.c. The drug was given on alternate days, the total quantity given being 20.5 c.c. to 46 c.c. The injections produced severe reactions resembling those of sodium antimonyl tartrate. The details of the three cases treated are given in the following table:—

blood remained absolutely unaffected, but the chyluria cleared up for the time being.

"Stibosan."

"471" (Von Heyden compound 471).

This compound is meta-chlor-para-acetylaminophenyl stibinate of sodium and contains 31 per cent. antimony in organic combination; Napier (1927) found it effective against kala-azar. The initial dose given in this series was 0.1 gm. in 3 c.c. distilled water administered intravenously; the maximum dose was 0.3 gm. in

TABLE III.
Antimosan. Von Heyden "661."

			Before Tr.	During Tr.	After Tr.				
I	24 H. M.	Chyluria ..	+	+	+	46 c.c.	Severe.	Chyluria cleared up for the time being.	
II	40 H. M.	Do. ..	Micro-filaria count per 20 c.mm. of blood	3, 8	2, 12	8, 20, 4	20.5 c.c.	Do.	Microfilariae disappeared from the urine.
III	28 H. M.	Lymph scrotum	Blood--No microfilariae present. Lymph from lymph scrotum showed microfilariae before treatment.			34 c.c.	Do.	No appreciable change in the size of scrotal swelling. Lymph could not be examined.	

A perusal of Table III will show that in all the patients who had the drug severe reactions, such as rigors, vomiting, rise of temperature, were produced. The embryos circulating in the

10 c.c. distilled water. The injections were given on alternate days or twice a week and produced little or no untoward effects. The results of the treatment are given in the following table:—

TABLE IV.
Stibosan "471."

Cases.	Age, Race and Sex.	Signs and Symptoms.	MICROFILARIA COUNT.			Total amount given.	Reaction.	REMARKS.
			Before Tr.	During Tr.	After Tr.			
I	20 H. M.	Lymphangitis, right leg.	+	+	+	1 to 15 gms.	Very slight	No effect on the microfilariae, slight improvement in chyluria.
II	32 H. M.	Lymphangitis, scrotum.	+		+	0.8 gm.	"	
III	19 H. M.	Lymphangitis, right leg.	+	+	+	2.05 gms.	"	
IV	29 H. M.	Chyluria ..	+	+	+	1.75 "	"	
V	26 H. M.	Lymphadenitis, right inguinal region.	+		+	2.95 "	"	

A perusal of Table IV will show that the drug was tried in five cases, the total amount of the drug administered, varying from 0.8 to 2.95 gm. The embryos circulating in the blood were in no way affected. One of the patients treated had chyluria and in him there was slight improvement; the urine cleared up for the time being, but the chyle soon reappeared. The drug had no immediate or remote effect on the microfilariae; some of the patients examined months after the treatment still showed microfilariae in abundance.

"Neo-stibosan," or Bayer 693b.

This compound is para-amino-phenyl-stibinic acid combined with an aniline, and is considered by Napier (1927) to be one of the most effective remedies against kala-azar. It was tried in two patients, the initial dose given was 0.1 gm. increased to 0.3 gm. intravenously. The injections were given daily for eight days to get the maximum possible concentration of the drug in the body. A perusal of Tables V and VI will show that the drug had no effect on the microfilariae in the blood.

"*Stiburea*" (Union Drug Company).

This compound has the same composition as urea-stibamine and is a combination of urea with para-amino-phenyl-stibinic acid. The initial dose given was 0.1 gm. dissolved in 3 c.c. distilled water, administered intravenously; the maximum dose was 0.2 gm. in 5 c.c. of distilled water. The drug was given every other day or twice a week and produced very slight reaction; the total amount administered was 1.2 gms. to 2.2 gms.

This preparation was tried in six cases and as all of them were attending the out-patient's department, the examination of the blood could not be carried out as regularly as in the case of

They were present in as large numbers in the blood of the patient after the treatment as before it. Chyluria cleared up with the first two doses of the drug and there was a slight reduction in the elephantoid swelling of the leg after treatment, but these effects were of a temporary nature.

"*Novostiburea*" (Union Drug Company).

Chemically this compound is a sodium salt of para-amino-phenyl-stibinic and urea. It is said to be more stable and does not decompose on exposure to air and can even stand boiling. The initial dose given was 0.1 gm. in 3 c.c. of distilled water, the maximum dose was 0.4 gm. in 10 c.c. of distilled water. The drug was given intravenously on alternate days or twice a week and pro-

patients in the hospital wards. The results given in the following table are sufficiently conclusive to show that there was no effect on the microfilariae circulating in the blood.

duced little or no reaction in patients; the total amount of drug given was 2.4 to 3 gms. The details of six patients in whom the drug was tried are given in the following table:—

TABLE VIII.

Novostiburea.

Cases.	Age, Caste and Sex.			Signs and Symptoms.	MICROFILARIA COUNT.		Initial dose gm.	Maximum dose gm.	REMARKS.
					Before Tr.	After Tr.			
I	17	AI.	M.	Lymphangitis, L. leg	+	+	0.1	0.4	Relapses during treatment. Do. Do. No appreciable effect on the Eleph. swelling. Elephantiasis of 32 years duration.
II	32	H.	M.	Lymphangitis, scrotum.	+	+	"	"	
III	20	H.	M.	Lymphangitis, L. leg	+	+	"	0.3	
IV	52	H.	M.	Lymphangitis, Eleph. R. leg.	+	+	"	"	
V	30	H.	M.	Lymphangitis, L. forearm.	+	+	"	0.4	
VI	26	H.	M.	Lymphangitis, R. leg	+	+	"	"	

The results were not encouraging. The patients under treatment suffered from repeated and severe attacks of lymphangitis, both during the course of treatment and after. The embryos in the blood remained absolutely unaffected. No one of this series of patients suffered from chyluria so that the effects on this condition could not be studied.

Antimony sulphur compound (Union Drug Company).

This is a soluble compound containing antimony and sulphur in organic combination. The initial dose was 0.1 gm. in 3 c.c. of distilled water given intravenously; the maximum dose given was 0.3 gm. in 10 c.c. of distilled water. The total amount given to the patients was 1.7 to 3 gms., injections being given every day. The administration of the drug produced little or no reaction.

only tried in two patients, 0.25 gm. to 1 gm. being given intravenously on alternate days. Only 6 injections of this drug were given, making a total of 2.75 gms. The drug produced rise of temperature and pain in the abdomen, but the urine remained free from albumen. The microfilariae remained entirely unaffected. Table X gives the details of these cases.

Mercurochrome 220 soluble.

This is an organic compound of mercury which can be given intravenously. Chemically it is dibromo-oxy-mercuric-fluorescein. This compound was tried in 3 patients who had embryos in the blood. It was at first given in 2 per cent. solution in doses of 1 to 2 c.c., but it produced marked reactions. We subsequently used a 1 per cent. solution. These were well borne, but the embryos remained absolutely unaffected, even after 10 c.c. doses.

TABLE IX.

Antimony sulphur compound.

Cases.	Age, Race and Sex.	Signs and Symptoms.	Microfilaria count daily.	Total amount.	REMARKS.
I	29 AI. M.	Lymphangitis, R. inguinal region.	44 16 65 18 21 75 125 98 72 12 42 per 20 c.mm. of blood. Mf. before Mf. after treatment. treatment. + +	3 gms. 1.7 "	No reaction. Do.
II	26 H. M.	F. lymphangitis, Eleph. R. leg.			

A perusal of Table IX will show that the drug was tried on two patients, one being a hospital patient and the other attending the out-patient department. The drug did not produce any reaction, nor any rise in temperature, as is usual

Plasmochin.

This compound is obtained from quinoline and is looked upon as alkamino-6 methoxy quinoline. The drug was given by the mouth, the initial dose given being 0.02 gm. in tabloid form,

TABLE X.

Bayer "205."

after the trivalent antimony compounds. The effect on the microfilariae in the blood was entirely negative:

Germanin or Bayer 205.

This drug is a complex organic combination and is believed to be a dye substance derived from amino-naphthalene sulphonic acid. It has well-marked trypanocidal properties. It was

three times a day. The patients were given a first course of 4 days and this was repeated after an interval of rest lasting 4 days. The drug did not produce any untoward effects on any of the patients.

This preparation was also tried in the Presidency Jail, Alipore, on prisoners with filarial infection who were otherwise normal. Twelve cases were selected, six received treatment and

the other six were kept as controls. A careful count of the microfilariae was made daily of both the batches. A perusal of the table will show that this drug produced little effect on the microfilariae circulating in the blood.

Further doses were given every week, the total amount of drug administered being 10 to 12 gms.

A perusal of Table XII will show that the twelve patients treated included those suffering from chyluria, filarial lymphangitis and elephan-

Emetine.

The effect of this drug has previously been tested. We tried it in 8 cases. In two of these it was given intravenously and in six by the subcutaneous route; in either case one grain of the alkaloid was given daily till six grains were given. No untoward effects were noticed, but the microfilariae remained unaffected.

Tryparsamide.

This is a pentavalent compound of arsenic which was developed in the Rockefeller Institute. Chemically it is sodium *n*. phenyl-glycinamide *p*-arsonic acid. The initial dose given was 2 gms. in 10 c.c. distilled water intravenously.

tiasis. Chyluria cleared up completely in every case and the very first dose produced disappearance of the microfilariae in the urine in 2 cases.

Cessation of chyluria has also been observed with the aromatic compounds of arsenic, such as those of arseno-benzene series, but the effect appeared to be more marked with tryparsamide. This drug is excreted in the urine in large quantities and probably acts by producing absorption of the proliferated endothelial cells lining the lymphatics and thus relieving the blockage to the flow of chyle. It appears to have no specific effect on the diseases, as microfilariae remain untouched and the elephantoid swellings are unaltered. Tryparsamide undoubtedly decreases

the frequency of the lymphangitis attacks and, therefore, is a drug worthy of further trial.

Summary and Conclusions.

From the data given above we are justified in drawing the following conclusions:—

(1) There are remarkable variations in the numbers of microfilariae circulating in the peripheral blood; these variations are quite independent of the drug which is being administered.

(2) Bisnene, antimosan, stibosan, neo-stibosan, stiburea, novo-stiburea, antimony sulphur compound, mercurochrome, plasmachin, emetine and tryparsamide produced no effect whatsoever on the microfilariae circulating in the peripheral blood and, it is therefore presumed, had no effect on the adult parasites.

(3) Tryparsamide, like some of the arseno-benzene compounds, produces disappearance of chyluria, and the effects with this drug often last for prolonged periods. This drug also decreases the frequency of attacks of lymphangitis.

We have much pleasure in acknowledging the help given by Lieut.-Col. N. S. Simpson, I.M.S., Superintendent of the Alipore Presidency Jail, in the course of this research.

BERBERINE SULPHATE IN ORIENTAL SORE.

By A. LAKSHMI DEVI, M.B., B.S. (Punjab).

LAHORE is one of the parts of the Punjab in which oriental sore is particularly prevalent and we have had many cases of this condition. We have until quite recently treated the condition by the application of antimony ointment or methylene blue, and by injections of emetine. These treatments were of long duration and, therefore, very tedious for the patients, and the success was doubtful. Acting on the suggestion of Lieut.-Colonel H. W. Acton, Director of the Calcutta School of Tropical Medicine, we have recently used berberine sulphate injections. This treatment has been really remarkably successful so far; the ulcer heals up as by magic with one or two injections only, and even in cases of long standing a marked improvement is seen a few days after the first injection. Very few need a third injection. The great advantage of this treatment is its cheapness and the ease of administration. We have followed exactly the method suggested by Colonel Acton; the margin of the ulcer is infiltrated by a 2 per cent. solution of the

acid sulphate. Details of the doses given in each case and of the progress of the ulcers under treatment are given below.

Case No. 1.—E., aged 8 years.

Ulcer on right arm, 1 inch in diameter, circular, with thin edges. The surface was covered with unhealthy glairy-looking granulation tissue and thin whitish discharge, the surrounding skin was indurated and $\frac{1}{2}$ inch to one side were two nodules pinkish and fairly soft covered with scales. These had existed for one year. On the left fore-arm was another similar ulcer $\frac{3}{4}$ inch in diameter, of shorter duration.

For 2 months these two ulcers were treated with the usual antiseptic treatment. Magnesium sulphate fomentations were used to clean them, and antimony ointment and methylene blue were applied in turn. The ulcers did not improve and on the right hand appeared two papules, probably secondary infections from the primary ulcers.

1st July, 1928.—The sore on the right arm was injected with 1 c.cm. of berberine sulphate solution. Two days later the ulcer was quite dry and appeared to have contracted in size. There were no constitutional symptoms.

After a week the induration around and the nodules had almost disappeared and the ulcer was covered with thin pink scar tissue. There was no scab on the surface.

10th July, 1928.—A second injection was given into the first ulcer and the ulcer on the left fore-arm was also injected at the same time.

21st July, 1928.—The first ulcer was quite healed, but as the scar was painful a third injection was given. The second ulcer reacted in the same way and was re-injected.

31st July, 1928.—Both the ulcers were healed; the scars were thin, sunken and painless, almost of the same colour as the skin. The nodules on the right hand were next injected; they healed up with one injection.

15th August, 1928.—The patient was discharged cured.

Case No. 2.—M., aged 27 years, mother of No. 1.

On the dorsum of the left wrist was an ulcer a little smaller than a silver two-anna bit. It was covered with a thin scab; the ulcer being shallow and of a uniform pink colour.

The edges were thin and there was not much induration round the sore. Duration 1 year.

Two days after the first injection of 1.5 c.cm. berberine sulphate there was a little swelling round the ulcer, which looked more moist and painful, but in a week it was much smaller, dry, and of a dull pink colour; it was then re-injected. A week later it was completely healed, the scar left behind being hardly noticeable.

As the patient complained of slight pain and swelling in one corner of the scar, a third injection was given on 9th November, 1928; this resulted in a complete cure.

Case No. 3.—R., aged 6 years, sister of No. 1.

A soft conical papule covered with scales, on left fore-arm. Duration 6 months. 0.5 c.cm. of the solution was injected. Two days later the papule looked much smaller and was dry. It was completely replaced by a painless thin scar in a week. No second injection was given. Another papule of the same nature and duration on the left thigh was similarly cured by one injection.

9th December, 1928.—Returned with an ulcer a little smaller than a two-anna bit on left thigh and $\frac{1}{2}$ inch from the one treated before. It was covered with a typical scab formed of scales and was surrounded by an areola of induration. Duration one month. After two injections of 1 c.cm. of berberine sulphate solution the ulcer was replaced by a pink supple scar.

These three cases occurring in one family may very well illustrate the infectivity of the condition.

Case No. 4.—S., aged 18 years.

A shallow ulcer the size of a two-anna bit on the dorsum of right wrist. The surface was of a uniform

pink colour covered with a thin discharge; no induration of the surrounding skin. Duration 1 year.

One week after an injection of 1.5 c.cm. the ulcer was completely replaced by a thin supple scar, without a scab.

A second injection was not given at the time.

9th November, 1928.—A month later a small pimple, size of a pin head, appeared on one corner of the scar and, as it was painful, a second injection was given.

The patient has had no further trouble.

Case No. 5.—R., aged 27 years.

A thick scar, size of a (silver) eight-anna bit, with a red nodule about the size of a pea in the middle; the patient had had Delhi sore for two years. CO₂ snow treatment was tried without much benefit and the patient had then had the ulcer excised. About 10 days after the operation the above nodule appeared and remained small and painful. After one injection the nodule had flattened down and the scar too was less thick and not painful.

After a second injection, a week later, the scar became very thin and pliable.

A month later a third injection was given as the patient was still suspicious of a slight pain on pressure over the scar. This case probably did not react so quickly owing to the presence of scar tissue resulting from the operation which may have had some influence on the penetrating power of the drug.

Case No. 6.—P., aged 23 years.

A small papule on the ankle for two months; after staying with a friend who had a Delhi sore, this papule burst and left an ulcer $\frac{1}{2}$ inch in diameter which is now surrounded by three similar ulcers and an indurated area for about half an inch all round.

3rd November, 1928.—One injection 1.5 c.cm. given.

7th November, 1928.—All the ulcers healed quite well; only the induration being still present.

14th November, 1928.—No induration present. No tenderness. Second injection not given.

Case No. 7.—T., aged 26 years.

Ulcer size $\frac{3}{4}$ inch by $\frac{1}{2}$ inch covered with thick black hard scab which was very firmly adherent to the underlying tissue. Edges thick and uneven. Dirty thin discharge. An area of induration bluish in colour and covered with scales for about $\frac{1}{2}$ inch all round. The ulcer was situated on the back of the elbow and the bones near by could not be felt due to the swelling.

Duration of the ulcer was two months; it was painless.

24th November, 1928.—Two c.cm. of berberine sulphate injected into the ulcer in 4 places; mag. sulph. fomentations were applied 4-hourly.

29th November, 1928.—The swelling around the ulcer had completely disappeared and the epicondyles of the humerus could be felt. The indurated area round the ulcer also felt softer and less marked.

On removing the scab there was a fair amount of bleeding and the granulation tissue underneath was unhealthy.

2nd December, 1928.—The ulcer was flatter and smaller. No swelling round about, and no induration or discharge.

A second injection was given.

8th December, 1928.—The ulcer much better though not quite healed. A third injection was given; the patient left the station.

11th January, 1929.—The patient returned and the ulcer was quite healed though thick. The same patient had three more ulcers on the right fore-arm. They were all in the papular stage. One was injected and healed with one injection.

Case No. 8.—S., aged 20 years.

A small papule which gradually grew bigger and formed an ulcer on the back of the neck.

Duration three months.

An ulcer about $\frac{1}{2}$ inch by $\frac{1}{2}$ inch covered with a dry scab formed of scales. On removing the scab the surface of the ulcer was seen to bleed readily and was covered with granulation tissue.

There was an area of induration for $\frac{1}{2}$ inch around. 13th November, 1928.—One injection of 1.5 c.cm. was given in three places.

16th November, 1928.—The ulcer flattened down.

20th November, 1928.—The ulcer looked much better and dry.

Second injection given in four places. Was dressed with boric ointment.

27th November, 1928.—Third injection given. The ulcer almost the same as on 20th November, 1928; dry dressing applied instead of the ointment.

12th December, 1928.—The ulcer covered with scab and smaller.

20th December, 1928.—The ulcer was almost healed.

It may be noted here that our cases do best with either dry or saline dressing.

Case No. 9.—P., aged 28 years.

A typical Delhi sore of six months' duration; partly healed after application of some Indian medicine. No further progress after the ulcer reached the present stage, three months ago.

A red softish and raised area of about the size of a four-anna bit.

No discharge.

3rd December, 1928.—Injection of berberine sulphate given.

10th December, 1928.—The scar darker in colour and quite flat. Second injection given.

17th December, 1928.—The scar looks much darker and quite flat.

Case No. 10.—K., aged 30 years.

An ulcer the size of an eight-anna bit on the back of left calf. It was flat, and covered with unhealthy granulations and dirty discharge. An area of induration for $\frac{1}{2}$ inch all round, not painful.

Duration—two months.

The ulcer did not look like a typical Delhi sore, but the Wassermann reaction was negative.

Three berberine sulphate injections were given, but the ulcer did not show any improvement. This was the only case of our series that failed to improve under this treatment and, as was noted above, it was not a typical oriental sore.

Case No. 11.—B., aged 1 year.

A soft red nodule the size of a four-anna bit on the dorsum of the nose.

Duration—two months.

After the first injection there was considerable reaction and much swelling round the ulcer which subsided after two days. A week after the injection the ulcer seemed better and smaller. A second injection was given but the patient did not return after that.

Case No. 12.—The patient is deaf and dumb and can give no history, but came from an institution where other cases had occurred. Two ulcers the size of a pea on the right arm. The surface was dry and scaly with a small area of induration around ulcers.

14th December, 1928.—One ulcer was injected with 1.5 c.cm. of berberine sulphate solution.

15th December, 1928.—The ulcer was dry and small.

18th December, 1928.—The ulcer still flat and small.

21st December, 1928.—Second injection given.

28th December, 1928.—Ulcer quite healed.

The second ulcer also was cured with two injections.

SUMMARY OF RESULTS.

Thus of the 18 sores treated on these 12 patients, six healed completely with one injection, five healed completely with two injections, five healed completely with three injections, while one improved with one injection but the patient did not return after the second.

One case only failed to show any improvement and in this case the original diagnosis was doubtful.

ON THE ANOPHELINE MOSQUITOES OF HAZARIBAGH (BIHAR AND ORISSA).

By BHUDEB CHANDRA BASU, M.Sc.,

Entomologist, Spirochaetosis Transmission Enquiry,
under Indian Research Fund Association,
Protozoology Department,

Calcutta School of Tropical Medicine and Hygiene.

DURING October 1926 and October 1928, the anopheline fauna of Hazaribagh was studied, chiefly from the entomological point of view.

Hazaribagh is a large sized town, covering an area of nearly 10 square miles and at an elevation of 2,000 feet above sea-level and lies between 23° 25' and 24° 47' N., and 84° 29' and 86° 38' E. The average annual rainfall is about 51 inches. The mean humidity is about 51. The day temperature rises as high as 107°F. in summer and falls as low as 40°F. in winter. But the climate is generally temperate. The town is situated on an elevated area and the land slopes away from the town and consequently

Anopheles pallidus, Theo.,
Anopheles theobaldi, Giles,
Anopheles maculipalpis, Giles,
Anopheles jeyporiensis, James.

The principal breeding places in the area are (i) large swamps, (ii) small streams which are very common in the outskirts and (iii) seepages which are also common in the outskirts of the town. The Hazaribagh Lake in the north-west and the Okni Swamp on the west of Hazaribagh are two prominent breeding places within the town. From the edge of these swamps to a considerable distance towards the middle aquatic vegetation is very thickly grown. *Anopheles fuliginosus* was found breeding profusely in the Okni Swamp as well as the Hazaribagh Lake. *Anopheles subpictus*, *barbirostris*, *hyrcanus* and *listoni* were also found breeding in these two places in October. The small streams at the outskirts of the town were found breeding large numbers of *Anopheles culicifacies* and a comparatively smaller number of

The Okni Swamp.

there is a good natural drainage in the outskirts of the town. There is, however, no proper system of drainage within the town itself, with the result that in the rainy season ample opportunities are afforded for mosquito breeding. Besides there are a few permanent breeding places, namely, the Hazaribagh Lake and the Okni Swamp where mosquitoes probably breed throughout the year. In the low-lying areas around the town several small streamlets flow.

Eleven species of anopheles have been found here, namely:—

Anopheles barbirostris, Wulp.
Anopheles hyrcanus, Pallus.
Anopheles subpictus, Grassi.
Anopheles vagus, Donitz.
Anopheles listoni, Liston.
Anopheles culicifacies, Giles.
Anopheles fuliginosus, Giles.

Anopheles listoni. These streams are evidently responsible for the adult *Anopheles culicifacies* which was caught in the town. *Anopheles theobaldi* and *maculipalpis* were found breeding in small seepages at the foot of the Canary Hill and the Sitagara Hill. Several wells in the town were examined but no larvæ were secured; the upper surface of water in the wells was at a considerable depth from the ground level.

Adult *Anopheles fuliginosus*, *culicifacies*, *listoni*, *hyrcanus*, *barbirostris*, *subpictus*, *pallidus*, *vagus* and *jeyporiensis* were collected from human habitations and cowsheds in the town.

In the adult specimens of *Anopheles fuliginosus* collected, a few variations were observed. The white area on the hind tarsals varied from 2½ segments to 3½ segments. In five specimens, instead of three usual palpal bands, four narrow palpal bands were seen. These variations

have been previously termed as a winter variation, and described as a variety, namely, *A. fuliginosus* var. *ædei*, but this view is no longer taken. These variations are frequent in *A. fuliginosus*. Some of the adult mosquitoes caught were found infected in the abdominal as well as thoracic regions, with red mites.

The local opinion points to the fact that Hazaribagh was more or less free from malaria

well-known sanatorium, and it ought not to be allowed to become malarious. Since the carrier anopheles as also malarial patients are present in good numbers, it is possible that if the present conditions are allowed to continue, Hazaribagh may at no distant date become as unhealthy as the neighbouring tracts of Singhbhum.

The writer's grateful thanks are due to Mr. M. O. T. Iyengar, Entomologist, Bengal Public

The Hazaribagh Lake.

a few decades ago and that of recent years, the malaria has been actually on the increase. The opinion of the local medical men, whom I consulted, also supports the view that during recent years, malaria cases have been increasing in number appreciably. The increase has been explained by the return of the coolies who are recruited for working in the tea gardens of the Bengal Duars and Assam, and who invariably returned home with a heavy malarial infection. It is very likely that this is to a large extent the proper explanation of the recent increase of malarial incidence in Hazaribagh. Out of the eleven species of anopheles found in Hazaribagh several species are known transmitters of the malaria infection. When so many of the malaria-carrier species occur in Hazaribagh and since the increase in malaria cases has also been very noticeable, it seems important that a detailed mosquito and malaria survey should be conducted in the town of Hazaribagh and its environs in order to understand the exact state of affairs. The present investigation was carried out during the vacation of the writer and, as such, is far from complete. Such a survey should be conducted to study the prevalence of the different mosquitoes at different seasons and the character of breeding places. The present paper is written with a view to drawing the attention of the public to the possibility of Hazaribagh getting more and more malarious in course of time if proper steps are not taken at an early date. Hazaribagh is an important holiday-centre and a

Health Department, for his help in connection with this investigation.

THE FATE OF THE MEROZOITES SEEN IN THE CULTURES OF MALARIAL PARASITES.

By R. ROW, M.D. (Lond.), D.Sc. (Lond.), O.B.E.,
Professor of Pathology, Grant Medical College,
Bombay.

(From F. D. Petit Laboratory, Byculla, Bombay.)

In another paper, the author of this memoir has described the various steps taken by the malarial parasites of all the three well known species, from the ring stage right up to a mature schizont and sporulator in a successful culture, and no further reference need be made to this beyond stating that the different phases of development (of the rings) not seen in blood films prepared at the bedside, in the case of *Plasmodium falciparum* infection can be studied accurately in cultures and with ease.

From a study of such cultures several factors underlying the variability in the number of spores developed in infections by the same parasite have come to light and these have been also dealt with in another memoir. In this memoir it is intended to indicate in broad terms some of the factors which prevent a successful culture, and the morphological changes which the parasite undergoes even when all the technical details are strictly adhered to. Such morphological changes may also explain not only the failures of the

auto-cultures, but also the difficulties one meets with in attempts to obtain successive generations of the parasite *in vitro*, strongly suggestive of the production of something antagonistic during infection.

The chief enemy the merozoite has to face, as it emerges out of a mature schizont, is the blood serum which strikes at the very root of the parasite's existence, viz., its chromatin, thus rendering it unfit to attack or thrive in a fresh red blood corpuscle. This serum action is seen even in the first culture, and appears as if specific, and one can well expect it to operate much more vigorously in the patient's blood which is being enriched every moment by the antibodies poured in, in response to the reaction of the infection. This antagonistic serum action may also explain why, although it is not unusual to have a recrudescence of the same attack 2, 3 or more times in a patient otherwise healthy, such reaction often comes to an end *per se*; it may also account for the complete want of proportion between the clinical features of each paroxysm and the capacity of the schizont to multiply, and where the yield of potential merozoites, setting up the second and succeeding paroxysm may be reckoned on a basis of 8 to 20 times or more each time. And lastly it explains the identical behaviour of the parasite and its degeneration in culture in an immune serum from a convalescent and in a quininized serum (Fig. 4).

The mature spore in a schizont is a spherical dot of chromatin with a thin rim of cytoplasm, and when it comes into contact with the serum it swells up and the well marked differentiation of these structures becomes confused, the chromatin dot becomes woolly and shows degeneration as seen by its taking up less of the nuclear stain and more of the eosin stain (Fig. 1 A); should the spores escape the action of the serum by their being protected by the remnants of the parent schizont, they are taken up by the phagocytes as are also the whole mature schizonts

altered nucleus and cytoplasm, both in structure and its acidophilic staining characters (Fig. 1 P). The merozoites which escape this double process of destruction are probably the ones which attack

Fig. 1.—A 48 hours culture of *P. falciparum* showing schizogony, escape of merozoites into the serum and the effect of serum action, and phagocytosis (P).

the fresh red corpuscle, and undergo fresh development into schizonts and sporulators. Such merozoites appear as though they had acquired a new rejuvenescence by passage through the phagocytes; but as indicated elsewhere, schizogony of the freshly infecting parasites becomes each time lessened until a time is reached when one

Fig. 2.—A 48 hours culture of *P. falciparum* showing the evolution of the crescents.

with their full load of spores, there to undergo the usual digestion and disintegration (Fig. 1 P and Fig. 3). In this process the phagocyte itself undergoes necrobiosis, as is seen by the

spore is capable of producing not more than one individual and this new direction of development leads to the production of gametes or crescents according to the infecting material (Fig. 2).

This phenomena comes about, however, only under special conditions, and as a rule in a fresh infection in an individual otherwise healthy the culture both *in vivo* and *in vitro* soon comes to an end. In the latter the dead phagocytes liberate a hæmolytic enzyme, which by dissolving the red blood corpuscles still intact in culture renders the whole tube laky (a sign that all the parasites are reduced to a granular debris interspersed with the persisting hæmozoin, this being the only index of their identity). This hæmolysis seen in a dying culture brought about by the degeneration and disintegration of the leucocytes as seen by their acidophilic stain, may perhaps explain some of the complex phenomena in the hæmoglobinæmia and hæmoglobinuria of blackwater fever, sometimes complicating a malarial infection.

In some individuals with a severe infection the blood is surcharged with rings and here one would expect a rich culture. It is found, however, that far from this being the result, the culture entirely fails, the majority of the parasites dwindling and degenerating. The only explanation of this is to be sought in the powerful antiparasitic qualities acquired by the blood serum, obviously induced in the course of the repeated paroxysms, because in experiments made with cross cultures with an indifferent serum, a better yield of schizonts and merozoites is obtained. Further, this anti-property of the serum is evident in the tendency of the parasite-laden red blood corpuscles to agglutinate in auto-cultures before they are destroyed by the action of the serum (Fig. 3). A similar agglutination

Fig. 3.—A 48 hours culture of *P. falciparum* showing agglutination of the schizonts.

is demonstrable in cross cultures made with a rich infecting material in a serum derived from a convalescent malarial case, where by the administration of quinine the blood serum is rendered doubly anti-parasitic.

In a cross culture of this nature it is remarkable to see the red blood corpuscles containing the *P. falciparum* rings clumped together in large masses visible even under low magnification; here

the parasites show a faint attempt to grow, but ultimately they degenerate. It may be of interest to note that one can obtain very rich cultures of merozoites by planting the parasite into sera

Fig. 4.—(A) A 48 hours auto-culture of *P. falciparum* to be compared with (B) as 48 hours hetero-culture of the same in quininized serum.

derived from patients with increased leucocytosis, e.g., pneumonia, localised inflammation and leukaemia.

Next to these two main factors, viz., the specific serum action and the phagocytosis, leading to failure of cultures, is the condition of hydræmia with its concomitant anæmia, vacuolation and distortion of the red blood corpuscles. Here the main failure is obviously due to the nutritional deficiency of both the serum, being poor in proteins, and of the red blood corpuscles in hæmoglobin.

Lastly, any obvious toxic contamination of blood serum also leads to a negative culture as seen from a comparison of the results of heterocultures and autocultures with sera derived from jaundice, both obstructive and hæmolytic.

From the above the following preliminary conclusions seem justifiable with regard to the essentials of a successful culture and possibly of a sub-culture:—

- (1) A vigorous parasite derived from a fairly fresh infection.
- (2) The culture medium (the serum properly glucosed) to be fairly unaltered in its biochemical contents, i.e., free from excess of water (hydræmia) and obvious extraneous toxic bodies like bile salts and bile pigments (jaundice), hæmoglobin and altered H-ion concentration and specific anti-bodies (agglutinins and other anti-bodies increased during each paroxysm).
- (3) A fair supply of fresh red blood corpuscles fairly rich in hæmoglobin.
- (4) Freedom from leucocytes in the first and subsequent cultures.
- (5) A rigid asepsis in all the manipulations.

This memoir is based on an investigation undertaken under the auspices of the Indian Research Fund Association, 1927-1928.

THE RESPONSE OF A GROUP OF INDIAN INFANTS AND CHILDREN TO THE SCHICK TEST.

A PRELIMINARY REPORT OF 186 TESTS.*

By V. C. RAMBO, M.D.,

Mungeli Arca Christian Hospital and Dispensaries,
Mungeli, Bilaspur Dist., C. P. (India).

I AM reminded, as I tell of such a few cases and with such little experience with the Schick test, of Dr. John B. Deaver, the Philadelphia surgeon, in whose scintillating lectures we, as students used to sit spellbound. Drawing himself up to his full height he would denounce the ignorant inexperienced physician or surgeon, who talks "too much, with the modification of the Litany, "Deliver us from the man who has had a case." However, to begin one must begin and so the following experience and observations are recorded, the first it is believed made on Indian children. Fox, McCombie Young, and McDonald made observations in Shillong on European and Anglo-Indian children, all of the school age. They also found that although the children tested had had among them in former years as many as forty cases in one year, there was no tendency for the disease to spread among the Indian children in an epidemic form although at the same time sporadic cases appeared among the Indian children population (Personal communication from Dr. E. C. R. Fox).

In the report of eleven cases of diphtheria in the Central Provinces, Rambo (1928), the question arises again, why was the spread of diphtheria so limited? It was to throw some light on this question that the 186 Schick tests were done. It has been said that only an expert can accurately judge the results of this test. However, after reading J. D. Rolleston's review of the Schick test in the *Medical Annual*, 1928, and, realizing that there were so many checks upon the tests and also that even an expert in a European country might have difficulty in judging the reactions on the tropical epidermis, it was determined to go ahead.

The Schick test material was obtained in very convenient form from Arnhold and Company, Bombay, agents for Mulford of Philadelphia. Fifty is the number for which each unit of the material is prepared. The control is found in a packet containing one ampoule and the toxin in another packet together with distilled water sufficient to dilute the toxin, together with complete directions.

In the first group of fifty, two Europeans were included so as to get, if possible, the text-book reaction and prove the potency of the material. In the other three groups of fifty, two other

Europeans were tested. Fortunately all but one of them gave perfectly unmistakable positive reactions, thus assuring us of the efficacy of the material used.

A few adult Indians are included among those tested, partly for the test's sake and partly because, at the time of injecting the test material, there were no more children to be had. As the material must be used quickly, it was thought advisable to use it up directly. The arguments used to get the village mothers to bring their children and infants to receive the tests would make an article in themselves. Suffice it to mention that at one time victory was snatched out of failure, when the chaprasi returned, saying no one would come, by my assistant going into two sections of the village and urging the mothers to come. The fact that forty-five children and infants appeared at the hospital within an hour of his visit proves a fine sense of appreciation on his part of a new scientific test and also his ability as a leader. Not all our tests could be given in the hospital. The last fifty were given in the homes and again my assistant made possible many tests that were allowed only with the greatest difficulty. They, however, became popular before we finished and one mother came after a group was completed asking that the child be tested also.

Throughout, the toxin was injected into the epidermis of the right forearm flexor surface and the control into the epidermis of the left forearm flexor surface. It might be well to explain that the control contains exactly the same substances as the toxin, except that the toxin was detoxicated by heating as mentioned below.

Quoting from Rolleston in the *Medical Annual*, 1928 "Four varieties of the Schick test are described, viz., (1) Negative; (2) Positive; (3) Pseudo, or negative and pseudo; (4) combined, or positive and pseudo.

1. The *Negative* reaction is a complete absence of reaction.

2. In the *Positive* reaction a red flush appears at the site of intracutaneous inoculation of diphtheria toxin within 24 to 48 hours and reaches its maximum in 40 days, when it forms a circumscribed swollen area measuring 1 to 2 cm. in diameter. It then slowly fades in a further 7 to 10 days to a circumscribed brownish tint with desquamation of the epidermis.

3. The *Negative and Pseudo* reaction develops rapidly both on the arm injected with toxin and on the control arm injected with toxin which has been heated to 75°. By the fourth day the reaction has mostly disappeared, but often leaves a reddish or brownish pigmentation with some desquamation.

4. In the *Positive and Pseudo* reaction the pseudo effect develops rapidly on both arms and as it fades the true positive reaction appears on the test arm.

(1) and (3) indicate immunity, and (2) and (4) susceptibility, to diphtheria."

* Read before the Mid-India Section of the Indian Christian Medical Association, Jubbulpore, C. P., 7th September, 1928.

Reading the tests.

There was among the younger children and infants not the slightest doubt about which test was positive and which negative. But among the children above three there were some cases that did not show the hearty reaction seen without exception in younger patients. This feeble reaction consisted of a single papule 0.3 by 0.4 cm. that appeared only on the arm receiving the toxin. This papule developed within the first twenty-four hours and disappeared leaving not the slightest sign, except that of the needle prick, by the end of 48 or 72 hours. These were called negative. In these occasional cases truly an expert is needed to pronounce proper judgment. Some of the children were not seen on the fourth day so that the reading made on the second or third day was counted final. This introduces probably a small error. Copeman, O'Brien, Eagleton, and Glenney (1922) made tentative readings in 24 hours in 400 cases and found that 5 per cent. proved later to be incorrect.

Concerning the positive reactions it would be well to say that in the darker epidermis this redness is combined with the degree of darkness of the skin tested in each particular case. In only one case was this reaction not present on the second day following the test. This case developed a positive reaction on the third day and continued the usual moving picture to the end of the test. Instead of the reacting area fading after the fourth day, the test becomes more and more evident, taking on a raised blackish purple colour on the fourth and fifth day and becoming almost a black area on a brown or olive skin by the seventh to ninth. From our experience we would say that this reaction is usually so definite, in younger children especially, that in case the examining physician could see the arm tested once only after the test, the examination at the end of the fourth to seventh day would show every case positive. This agrees with the report of the Schick test given in the Medical Research Council's monograph on diphtheria, page 362. In the children above four later signs of the reaction were not so marked and often did not scale typically and did not leave any hyperpigmentation. The hyperpigmentation lasts in many instances for a month, or longer in the marked cases.

Only two *Negative and Pseudo* reactions were seen. In these cases a slight papule 5 cm. in diameter appeared on the fourth day, in both arms exactly the same. The reaction lasted for three days and entirely disappeared simultaneously leaving no pigmentation or trace whatever.

No *Positive and Pseudo* reaction was seen in our series.

The group tested included the entire household of the pastor mentioned above whose daughter had diphtheria. P. S. the pastor, S. B. his wife, V. S. his son of five, and the youngest daughter just 15 days old were all *Negative*. The girl who had had diphtheria in February 1928 as mentioned above was *Positive*.

Statistics.

Schick tested children and infants, including a few adults.

Age group.	Number tested.	Number positive.	Pseudo-reactions.	Per cent. positive.
1-3 months	7	1	0	14
3-6 "	8	0	0	0
6-12 "	12	8	0	66.6
1-3 years ..	45	25	0	62
3-6 " ..	28	3	0	10.7
7-10 " ..	36	5	0	14
11-14 " ..	38	1 plus - minus, very slight react on yet apparently <i>Positive</i> .	1 <i>Negative and Pseudo</i> .	2.6
15-20 " ..	12	0	0	0
Total children and infants.	185			
21-30 years.	4	0	1 <i>Negative and Pseudo</i> .	
31-40 "	1	0	0	
41-50 "	1	0	0	
51-60 "	1	0	0	
Total Indians.	193			
European adults.	4	3	0	
GRAND TOTAL	197			

As this is such a small number of cases, percentages are not to be considered to be accurate, but they are an indication as to the approximate findings that may be expected in a larger survey.

One of the striking things is the small percentage of the children of the groups from the age of four and up who are susceptible. This is the roaming age and it may be because of this fact that there are fewer cases and that when a case does appear it does not spread as it might possibly otherwise do if these older children were more susceptible.

Of the seven-to-ten-year children two in the boarding school, who were found positive, are said to be the most slovenly and ill kept of the entire boarding school.

For the apparently high immunity of the infants under 6 months, I have no explanation except that perhaps the average Indian mother may be endowed with a high anti-toxin creating power which she transfers to her infant through her milk. After six months the infant has an opportunity to get other food and after nine months *dal* and rice even are given by mothers, especially those who do not have enough milk for their offspring.

The statistics on the frequency of the Schick reaction among the populations of different countries furnish results essentially different. The marked increase during the period from the second year of life to the beginning of school, as brought out by the American statistics, is entirely lacking in the German statistics.

In the statistics presented for India there is a very marked decrease of susceptibility before the sixth month and after the third year. In making comparisons the fact is again evident that insufficient statistics are at hand to make comparison with the statistics taken from the multitude of cases recorded in Germany and in America. It is hoped that others may make and report observations of Schick tests until sufficient statistics are available. Unfortunately there were no statistics of other nations at hand in the station to present for further comparisons.

Age group.	American Statistics.	German Statistics.	Our Statistics.
1-3 months ..	15%	21.5%	14%
3-6 " ..	30%	44%	(Insufficient data) 0%
6-12 " ..	56-91%	42%	66.6%
1-3 years ..	83%	43.4%	62%
4-6 " ..	53%	45%	16.7%
7-10 " ..	36%	41%	14%
11-14 " ..	22%	29%	0%

It might be interesting to quote from the results among European and Anglo-Indian children obtained by Fox, McDonald, and McCombie Young in Shillong.

Showing the number of positive Schick reactions and pseudo-reactions according to age.

Age.	Number tested.	Number positive.	Percentage of pseudo-positive.	Number reactions.
1-5 years	11	6	54.5	0
5-10 years	97	50	51.5	3
10-15 years	137	57	41.5	5
Over 20 years	6	4	66.6	2
TOTAL ..	271	125	46.1	12

Conclusion.

To-day, September 4th, the author has lost a case of diphtheria, an Indian child. ("The smears show a few diphtheria bacilli" is the report returned by Major G. Shanks, of the Department of Pathology and Bacteriology, Medical College, Calcutta, thus confirming the diagnosis). In spite of the fact that he has been concentrating on the Schick test and diphtheria for the last two months this case was enough to trip him and the anti-toxin was not given in time to stay off a cardiac paralysis. This goes to show that the results of such an investigation as above presented may not be untimely, warning us all

again that there is a very large group of little children and infants around us that are susceptible to this serious and often terrible disease. It also indicates that in looking for diagnoses, the throat should be one of the places routinely examined and when in doubt anti-toxin should be given.

This report seems to indicate that in efforts for prophylaxis the children belong to the group from six months to four years should receive the prophylaxis treatment first. There is no question that this susceptible group should be Schick tested and those with positive reactions should have toxin, anti-toxin or the toxoid as a permanent protection. Before making any deductions about the older "school age" children more statistics are required, and the writer would urge all those in charge of schools to do the Schick test and give their results together with their experiences with diphtheria so that some intelligent conclusion may be drawn to guide us with this problem. There are many unknown factors in this matter that need further investigation. Why is not diphtheria more common? There is probably much more diphtheria around than we notice.

A Mirror of Hospital Practice.

A CASE OF POST-KALA-AZAR DERMAL LEISHMANIASIS.

By NEPAL CHANDRA DEY,

Sub-Assistant Surgeon, on Kala-azar Duty, Assam.

A CASE of dermal leishmaniasis after a cure for kala-azar has been effected, is a rare condition; still rarer in Assam. In my experience extending over a period of four years as a Sub-Assistant Surgeon on kala-azar duty in the most heavily infected areas of Nowgong (Assam) district, which is admittedly a renowned epidemic area for kala-azar, and where treatment and survey are both constant and intensive, I have come across only this one case:—

C. R., aged 12 years, Hindu, male, from Nowgong (Assam).

Chief complaint:—

(1) Brownish discoloration of the skin in patches of 1 inch diameter over the entire

body except the trunk where there were a few very small depigmented spots.

(2) Discrete nodules on the lips, inner side of the elbow joints and on the anterior aspects of the knee joints.

A confluent diffuse type on the dorsal aspects of the wrist joints, extending from about 1 inch above the wrists to the tips of the fingers and also on the similar aspects of the ankle joints, extending from about 2 inches above the ankles to the tips of the toes.

Family History.—One brother died of kala-azar.

Previous Illness.—Suffered from kala-azar and was cured after a course of injections of sodium antimony tartrate.

Previous Treatment.—Received three injections of sodium hydnocarpate: case was diagnosed as leprosy.

Duration of the Disease.—About four years.

Nature of onset.—Four months after being discharged cured of kala-azar the patient noticed very small depigmented spots on the lips, chin, arms and forearms, thighs and legs and last of all on the trunk. These spots grew larger. Subsequently these patches were replaced by nodules on the lips, backs of the wrists, dorsum of the feet, anterior aspects of the knee joints and inner aspects of the elbow joints.

Spleen.—Not palpable.

Liver.—1 inch below the right costal arch.

Aldehyde test.—Negative.

Urea Stibamine test.—Positive in 5 and 10 dilutions of serum with 4 per cent. solution.

Total W. B. C. count.—8,600.

Different W. B. C. count.

Polymorphonuclears	..	62	per cent.
Small lymphocyte	..	18	" "
Large mononuclears	..	12	" "
Eosinophiles	..	8	" "

He had goitre before the attack of kala-azar.

Now I suspected the case to be one of dermal leishmanoid. I next prepared six slides from the cut surface of a nodule and after staining with Leishman's stain, I found Leishman-Donovan bodies on examination in large numbers in various forms. I was struck by the fact that the first slide which contained numerous blood cells was the one in which Leishman-Donovan bodies showed up best and were plentiful.

On examination the characteristics of the parasite were as follows:—

1. They were all extra-cellular.
2. The parasite was often seen in clusters of 8 and 9 lying between cellular tissues.
3. Many of them were almost at the point of complete division. (Two cells connected by a bridge of cytoplasm.)
4. Some were at the beginning of division (double nucleus and double kinetoplasts).
5. The nuclei were spongy in appearance in lightly stained specimens.

Treatment.—The boy was discharged clinically cured after receiving 2.4 grms. of urea stibamine (Brahmachari). All the nodules and depigmented spots disappeared and the general health of the patient improved very much.

My thanks are due to Dr. P. K. Das, Sub-Assistant Surgeon, Jajari K. A. Dispensary, for kindly communicating the result of treatment.

Note.—This case is of special interest in view of the apparent rarity of the disease in Assam. At the Calcutta School of Tropical Medicine we have notes on well over 100 cases collected during the last 3 years.—
EDITOR, J. M. G.

A HEART CASE—FOR DIAGNOSIS.

By PROVAT CHANDRA BAGCHI, L.M.F.,
Madaripur Charitable Dispensary, Malsara P. O.,
Dist. Rajshahi, Bengal.

I SEND the following notes of a case for diagnosis, and I believe it will certainly provide some interest to readers of this paper.

The patient, a fair-skinned Hindu girl, age 11 years, not well-nourished. Height 4 ft. 3½ inches, chest 1 ft. 11½ inches. Forehead prominent, lips thick, nose flat, eyes prominent and congested. A peculiar ashy pigmentation of the skin over the alæ of the nose, lobules of the ear and external canthi of the eyes can be noticed. The face is cyanosed and the venules are distinct. The fingers and toes are abnormally long, clubbed and cyanosed. There is overgrowth of nails present.

Endocrine deficiency and the other causes of osteo-arthritis being eliminated, her present condition could be referred to one due to heart disease—chronic or congenital.

Past History.—She has never been a subject of rheumatism—acute or chronic, nor of congenital syphilis. Her parents—as they say—are absolutely free from either of the diseases.

Present Complaints.—Dyspnoea and palpitation on slight exertion, sometimes paroxysmal. Aching pain of the bases of the ungual phalanges occurs in pyrexia from any cause.

CHEST.

Lungs.—Are resonant throughout except at their bases where there is moderate dullness and the vesicular murmur cannot be heard.

Heart.—The apex-beat is visible in the 5th interspace—left, 1 inch lateral to the mid-clavicular line. The cardiac dullness extends from the mid-sternal line to the apex = 4 inches. Auscultation reveals a systolic bruit all over the præcordium except the apical region. This bruit is of rough, grating character and is loudest over the pulmonary area. Pulmonary second sound is loud and distinct. At the apex and over a very small area a pre-systolic bruit can be distinctly heard—the systolic sound is neither replaced nor is the bruit present with it. The systolic bruit can be heard throughout the left

half of the chest in front and is conducted through the carotids and the subclavian arteries.

Pulse.—Regular, volume—small, tension—moderate.

Now the majority of the above clinical signs and symptoms refer to the presence of congenital pulmonary stenosis, but I should be glad if any reader of this paper can account for the presence of:—

- (i) Pre-systolic murmur at the apical area.
- (ii) Conduction of the murmur through the carotids and subclavian arteries.
- (iii) Loud and distinct pulmonary second sound.
- (iv) Aching pain at the bases of ungual phalanges occurring in pyrexia from any cause.

[*Note.*—Some of the signs and symptoms suggest patent ductus arteriosus.—Editor, I. M. G.]

A CASE OF BLEEDING FROM THE BREAST.

By D. N. SINHA, M.B.,
and

R. K. MUKHERJEE, S.A.S.,
Suri Sadar Hospital, Birbhum.

On the 11th October, 1928, an old out-door patient Khudan Bibi, Mohammedan female, aged 50, came to the out-door with the following complaints:—

- (1) She has been bleeding almost continually from the venous blebs on the surface of the left breast for the last one year.

- (2) The left breast feels tense and slightly tender.

- (3) There are venous blebs on the surface of the breast.

Past History.—She used to menstruate regularly but it stopped 12 years ago. During the last 4 years she has had bleeding from the left breast. For the first 3 years she bled regularly 4 days a month. For one year she has been bleeding continually.

Personal History.—She has only one child, still living. Her husband died 35 years ago. She denies gonorrhœa and syphilis. She has been fairly healthy throughout her life.

Local Examination.—The left breast looks enlarged, tense and a little tender. There are angiomatic venous blebs present. These disappear on pressure. There is no ulcerous area nearby. The breast is not hard to the touch and there are no enlarged glands present anywhere throughout the body.

The patient again came on the 28th of October with fever. Her blood was examined and malaria parasites (B. T.) were found. She was treated by quinine. Her fever was cured in a few days but to our surprise we learnt she has stopped bleeding from the breast.

In conclusion, we beg to thank our chief colleague, Dr. W. A. Browne, Civil Surgeon, for kindly allowing us to publish the case.

A CASE OF UNUSUALLY LARGE CYSTIC GOITRE.

By G. M. IRVINE,
CAPTAIN, I.M.S.,

Indian Military Hospital, Bakloh.

THE following case may prove of interest as an example of unusually large cystic goitre.

The patient was an elderly "pahari" whom I met casually when on a shooting expedition outside the cantonment. Being interested in the unusual appearances of the tumour, I persuaded him for a small consideration to come to be examined and photographed.

He was unable to give a very intelligible account of himself. He thought he was about 50 years old and stated that he had had a swelling in his neck from boyhood, since which time it had increased imperceptibly to its present dimensions.

A large tense cystic tumour of regular outline, about the size and shape of a foetal head projected forward from the left side of the neck. It was extremely vascular, the skin over it being covered by a network of tortuous and dilated veins, to a greater extent even than that suggested by the photograph. In the normal position of the head it extended from the lower border of the body of the mandible above to the level of the 2nd intercostal space below. A definite thrill was elicited.

The tumour was found to have its origin in the left lobe of the thyroid gland and followed the movement of the larynx in deglutition as far as its bulk would permit it. The larynx was displaced to the right but not

markedly so. The right lobe of the gland showed a marked general enlargement which

presented the usual features of a parenchymatous or colloid goitre with cyst formation.

Of symptoms referable to the tumour, the most important was stridor, due to a lateral pressure on the trachea. This was apparent at rest, and became more marked on exertion. The patient, however, complained of no embarrassment of his breathing and stated that it did not curtail his activities in any way. There was no history of that sudden obstruction during the night which is seen in large goitres, such as this, when the sufferer assumes during sleep a position which allows the weight of the tumour to fall on the trachea and compress it.

The tumour by its size interfered mechanically with the movements of the head. Any attempt to flex the head beyond the normal position of rest brought the mandible into contact with the tumour and restricted the movement; this did not appear, however, to inconvenience him greatly.

There were no general symptoms pointing to hyper- or dysthyroidism. The condition, pathologically, was presumably one of a cystadenoma arising in a gland which was in a condition of colloid parenchymatous goitre. The case was encountered in a region in the foot-hills of the Himalayas in the Northern Punjab where goitre is endemic, and where a large percentage of the indigenous population suffer from the condition in greater or lesser degree. Even in this locality where extreme enlargements of the thyroid are common a tumour of such dimensions was sufficiently remarkable.

CONGENITAL DEFICIENCY OF TWO FINGERS AND THEIR METACARPAL BONES.

By JAMAL-UD-DIN,

MAJOR, I.M.S.,

Civil Surgeon, Attock District, Campbellpur.

X, MALE, aged 35, actually came under observation in another connection.

Both the feet and the right hand were all perfectly normal in all respects. The left hand, as is clearly shown in the accompanying photograph, was however incomplete in so far as both index and middle fingers as also their two metacarpals from the carpo-metacarpal junction downwards were all missing: so far as one could make out the carpus was normal in all respects. Unluckily the part could not be x-rayed, but only 11 bones of the hand could be counted.

The defect was congenital.

He was the only member of the family who was born with this defect and all the other members were in all respects normal.

No actual discomfort was noticed by him and the defect was no handicap in his work.

Both thenar and hypothenar eminences were unduly marked and the latter only to a degree faded towards the roots of the remaining fingers.

The defect, like others about this region, would appear to arise from intrauterine amputation by amniotic bands and can hardly be considered to be due to arrested development in utero—a possibility however which cannot be excluded.

Indian Medical Gazette.

MARCH.

THE ILLNESS OF H. M. THE KING-EMPEROR.

Now that H. M. the King-Emperor has been safely transferred to a quiet, and, we hope, uninterrupted convalescence at Bognor, in common with every journal in the British Empire we may breathe a prayer of the most profound thankfulness for so happy an issue. Only those who lived through the weeks of December, 1928 in London can realise the state of terrible anxiety which prevailed in the capital city. There was no other topic of conversation, and night after night the anxious crowds gathered at Buckingham Palace to see the 9-30 p.m. bulletin, rich and poor alike, women wrapped in furs who stepped out of their luxurious cars, women in rags, crowds from the closing theatres or those on their way home from a dance.

At the Armistice Day ceremony on November 11th, His Majesty looked frail and careworn, though as kingly as ever. The morning was one with a slight drizzle, and it is possible that exposure to the weather that morning may have contributed to the illness. The first bulletin—issued on the evening of the 21st November—announced that His Majesty was suffering from what is popularly termed “a feverish cold.” By the 21st of November, there was definite congestion at the base of the right lung, with pleural friction. There was a serious increase of the pleurisy by the 24th of November, and finally two-thirds of the right lung was involved. By the same date the diagnosis had been confirmed by bacteriological tests and x-ray examination.

An illness of such severity in a patient aged 63 was naturally one in which only a very guarded prognosis could be given. We owe His Majesty's fortunate recovery to three chief factors, the highly skilled medical attendance provided, the magnificent nursing, and His Majesty's own determination to live. To these we must add the devoted service of Her Majesty the Queen.

By the third week of illness the clinical picture was complete, that of an extensive pleurisy in the right lung, with a streptococcal infection of the blood stream. The pleurisy had extended to the diaphragm, causing severe pain, and attacks of bronchial spasm. The whole issue now turned upon the heart muscle, and every possible measure was taken to ensure the utmost rest and sleep. By the 5th of December, the local signs in the lung appeared to be improving, but the general toxæmia was profound. A period of temporary improvement of the local condition,

however, was followed by an increase in the fever and the leucocytosis, and the development of an empyema was suspected. Pus was finally found, and drainage effected by rib resection, the operation being carried out by Sir Hugh Rigby, and the general anæsthetic given by Dr. Francis Shipway. The next forty-eight hours were naturally ones of acute anxiety, but there was no increase in the weakness.

There next set in a prolonged period of ebb and flow of the illness. The bulletins were most carefully guarded in tone, but the general public, reading between the lines, knew how critical was the situation. An authoritative bulletin was issued to the medical press on the 19th of December, and as it gives a very complete account of His Majesty's illness in general, we take the liberty of quoting it from p. 1151 of the *British Medical Journal* for the 22nd of December. The bulletin was as follows:—

“There are signs that the King's illness is producing in the public mind a sensitiveness, only too natural, caused by weeks of anxiety, and producing too easily alarm and therefore distress, both of which it is most desirable to avoid. Doctors, in their various spheres, can do much, by their knowledge, to maintain hope and confidence.

“The present condition of His Majesty can be best understood by recalling earlier stages of this severe illness. In the first phase, gradual in its onset, there were to be noted general infection with imperfect localization—little or no cough and only one small patch of pleuritic friction; blood culture positive (streptococcus); an irritative state of the nervous system which produced profound distress and sense of illness. Yet with these was a wish, born of quiet courage and the habit of duty, to make light of the illness and hold on to work, thus adding to the wear and tear of the fever. Towards the end of this first phase came an accentuation of pleuritic friction which extended to the diaphragm. The second phase was one of increasing toxæmia, with dusky appearance, dry cracked tongue, periods of delirium, exhaustion—in short, a clinical picture resembling that of a case of severe typhoid fever in the third and fourth weeks, but with the added anxiety of attacks of dyspnoea and cyanosis, due to strain on the heart. With the next phase came an abatement of fever and some evidence of localization. The blood culture was now negative, toxæmia was less, delirium subsiding. The localization in the right lung did not result at this stage in effusion, as shown by puncture and excellent radiographs. A few days later the temperature rose rather abruptly to a higher level, and on 12th December, there was evidence at the extreme right base of an effusion which had commenced between the lung and the diaphragm. Drainage by means of rib resection was performed on the same day under general anæsthesia (gas-oxygen-ether). The predominant organism in the empyema has now been established to be identical with the streptococcus found in the blood.

“Though the infective process has become gradually localized, its severity, coupled with the lowered vitality resulting from the length of the illness, must make the progress of healing difficult and tedious. Local sloughing, however, is less pronounced to-day, and tissue reaction apparent. To stimulate vitality of tissues a brief general exposure to ultra-violet rays from a mercury lamp has been made each day since 15th December. The effect of these exposures is being checked by leucocyte counts and estimation of the bactericidal power of the patient's blood. There is reason to think that this employment of the ultra-violet rays has, in combination with the treatment mentioned in previous statements, been beneficial,

"It is hoped that the foregoing account will help towards an understanding of the future course of the illness. It will be apparent to medical men that not only the severity and length of the infection, but the exhaustion resulting therefrom, must make progress slow and difficult. At the same time, dangerous phases of the illness have been surmounted, and there are increasingly solid grounds for hoping that recovery will result from this long and anxious struggle."

The week following Christmas, however, saw a slight, but marked improvement, and the bulletins were shorter and were issued at longer intervals. A supplementary report was issued to the medical profession on the 2nd of January, and read as follows: (*British Medical Journal*, 5th January, 1929, p. 31).

"For true understanding of the position it must be emphasized that neither in its inception nor in its subsequent course has this illness conformed to what is called 'pleuro-pneumonia'; rather was it a streptococcal septicæmia which by fortunate happening localized at the base of the right lung, first imperfectly and later as an empyema ('fixation abscess') forming between the base of the lung and the diaphragm. In the second phase of the illness (*vide* report 22nd December) the clinical picture—dusky appearance, dry cracked tongue, delirium, subsultus, exhaustion—was that of a severe toxæmia, and resembled that of a case of severe typhoid fever in the third or fourth week. So now the picture is that of the aftermath of a severe general infection. The empyema wound is now clean and steadily diminishing in size, the discharge from the pleural cavity is small in amount, and the streptococcus grown from the pus (identical with that originally found in the blood) is diminishing in potency. Eusol has been an effective local application, and though—through the courtesy of an American colleague, Dr. Sherman of Pittsburg—a supply of Dakin's solution, electrolytically prepared, has been recently received, there has been no opportunity to use it because the necessity for any such local application has passed.

"On the other hand, the disinclination for food and the dryness of the tongue, the low blood pressure, the weakness and wasting, the notable exhaustion, though slowly improving, will for long be an anxious problem. It will be readily understood that while this exhaustion state is pronounced, the margin of reserve power must be narrow, and that small set-backs, inevitable at this stage, have a correspondingly more severe effect. It is important that the public should not interpret such set-backs or reports of 'no change' as relapses. During each week there will be ups and downs, and progress will consist of a slow and increasing predominance of the ups over the downs. One of the inevitable difficulties in so long an illness is to convey to the public a true picture—neither too bright nor too dark. It is for this reason amongst others that the courtesy of the medical press is valuable, in order to convey through their readers to the public fuller information, and so avoid the risk of misunderstanding.

"As regards nourishment, about which so many suggestions have been received, the difficulties will be understood when it is stated that there is disinclination for most foods and dislike for many, and that weakness necessitates that nourishment be given by a nurse with a feeder. Adequacy of nutriment, both as regards quantity and variety, is now being secured, though not without difficulty. Moreover, the combating of loss of weight, which has been notable, depends not only on food taken but food digested and assimilated, and here again the exhaustion tells its tale. The blood-pressure has fallen too low and the calcium content of the blood has of late considerably decreased. The administration of calcium, parathyroid extract, and strychnine is apparently beneficial. The same is true of

ray therapy, which is being continued. It need hardly be stated that the question of blood transfusion has received full consideration. In an illness of this complicated character the indications for transfusion must be clear, and it must be remembered that with the most skilled procedure its employment would in this case entail risk. The striking results following transfusion—for example, in cases of anæmia due to either hæmorrhage or infection—are apt to lead to its employment in other conditions without adequate consideration of the pros and cons. It is sufficient to repeat that in this grave illness it has been fully considered, and put aside at the present stage as definitely undesirable. Moreover, the red blood cell count is one of the most hopeful features, for whereas in the early days of the illness the red count was as low as 2,900,000, to-day it reaches 4,300,000.

"The exhaustion is as much a weariness of mind as of body. Though there is an increasing sense of the burden of his illness, the will of the King to live is there. Because of this exhaustion the course must be long and for the present anxious. None the less, improvement and progress are taking place slowly but surely enough to justify the hope that the King will be restored to his people."

The subsequent course of His Majesty's illness was a very slow and gradual improvement, although anxiety still continued. By the middle of January the bulletins recorded quiet days and a more hopeful outlook than at any time during the previous seven weeks. Finally it proved possible to move the patient by ambulance to Bognor on 9th February, where at Craigwell House he will enjoy whatever sunshine the South Coast affords, and the refreshment of a complete change of scenery and environment. The bulletin of 13th February recorded that "His Majesty's progress is such that he is now able to read occasionally. He is on ordinary diet and takes plenty of nourishment." The only danger that still appears to exist in connection with the case is the terrible weather at present prevailing in the British Isles, though one may be certain that every possible precaution will be taken.

The medical profession may take a legitimate pride in the marvellous recovery made by the King-Emperor. We do not believe that ten years ago medical science could have brought about such a recovery.

SPECIAL ARTICLE.

THE PRESENT POSITION OF MEDICAL SCIENCE IN INDIA.*

By C. A. GILL, D.P.H.,

LIEUTENANT-COLONEL, I.M.S.,

Director of Public Health, Punjab.

WHEN I was asked to deliver this lecture I gladly consented to do so, but not being actively engaged in general practice, I felt under some difficulty in regard to the selection of a suitable subject. I thought, however, that it might perhaps be permissible, as a change from the usual

*A lecture delivered before the Punjab Branch of the British Medical Association on 23rd January, 1929.

clinical lecture, to consider the present position of medical science in India.

It may seem, at first sight, that this subject is not one which lends itself to fruitful discussion by the members of the British Medical Association. We, at any rate, are confident of the strength and soundness of our position, and, in view of the number of Medical Colleges and Schools established in India, of the rapid multiplication of hospitals and dispensaries, and of their increasing popularity, it would seem that medical science is strongly entrenched in India. But not everyone shares these optimistic views. They point to the fact that there are powerful reactionary forces at work, that quackery flourishes like a green bay tree in Lebanon, that the medical profession is overcrowded, and that many private medical practitioners eke out a precarious livelihood. It may, therefore, be worth while to take stock of the situation, to trace the history of medical science in India, and, having then clarified our ideas in regard to the past, to consider briefly the present and the future.

I make no apology for making a digression into the past; we stand to-day the heirs of the past, and what we do to-day may make or mar the morrow; neither the present nor the future can, therefore, be understood except in relation to the past. We are moreover all so pre-occupied with the daily round and common task that few of us have the time or the opportunity of studying the history of our science. Indeed, I doubt if any other body of scientific men are so little acquainted with the history of their own science as the medical profession, and I cannot help thinking that this circumstance is responsible for many misconceptions and misunderstandings.

The early history of medical science, as of the human race itself, is fragmentary and incomplete, and it may be that existing views on the subject will have to be extensively revised in the light of future historical research; but, if it is permissible to base conjectures upon the little that is known, it would appear that as soon as man became endowed with the power of reflection, he began, by the familiar method of trial and error, to devise simple methods of alleviating the ills the flesh is heir to, and to formulate theories in regard to their causation. Shrewd observations and practical deductions were thus made at an extremely early period in the history of the human race, and, as might be expected, they were first mainly concerned with curative measures. Many examples might be quoted, but two must suffice: it is to the primitive inhabitants of Peru that we owe the discovery of the value of the bark of the cinchona tree in the treatment of malaria. Then again, the value of inoculation as a protection against smallpox was first discovered in India where it has been practised since an extremely remote period.

It may be assumed that speculations and observations were made to some extent in all quarters of the inhabited globe, but it is permissible to infer that they attained a relatively high degree

of perfection amongst the more culturally advanced races. We would therefore expect that the ancient civilizations in the south of Europe, Asia Minor, Mesopotamia, India and China would have played a prominent part in the early history of medicine. It was indeed commonly held until quite recent times that the south-east corner of Europe, and more particularly Greece, constituted the birth-place of modern scientific medicine, but the tendency of modern historical research is to assign a rôle of increasing importance to the part played by Asia and more particularly by Mesopotamia, India and China.

So far as India is concerned, the oldest extant literature is to be found in the Vedas, which are believed to have been compiled about 4,000 years ago or more than 1,000 years before the birth of Hippocrates, "the father of medical science." The Vedas, however, contain little of scientific value, but the fourth book (The Atharvaveda), which deals mainly with magic and spells, contains some rudimentary anatomical and physiological observations. The writings of Sushruta, who lived at Benares, in the sixth century B.C. are, however, on a different plane, and compare not unfavourably with the Hippocratic "collection" of a slightly later date. In the case of both it may be said that they show evidence of centuries of scientific thought and research in medical matters. We can thus trace the small beginnings from which modern medical science has sprung to a common source in Europe and in Asia. Its subsequent history in the two areas, although still obscure, presents several features of great interest. In India, in addition to the followers of the physicians Sushruta and Charaka, the surgeon of Kashmir, and others, there arose another school of thought, who attributed medical knowledge to divine inspiration and revelation and, as a consequence of the fact that this latter school came to exercise a predominant position, medical science early came under priestly control and its scientific aspect dwindled and decayed. It is so much easier to make claims of divine power, and, in a primitive state of society, to establish them, than it is to undertake laborious investigations. But whatever the cause, in the East sacerdotalism soon obtained complete mastery and the dissection of human or other bodies was forbidden on the grounds of ceremonial uncleanness. Any advance on the crude anatomy and physiology of the Vedas thus became impossible and medical science became lost in a maze of speculations and theories whose accuracy could never be tested. The Vedas were in fact regarded as sacrosanct and any attempt to advance medical knowledge was considered as not only useless but even profane. In such an atmosphere medical science had little chance. The scientific spirit gradually died out and the Ayurvedic system—a system as truly scientific as that developed in Greece—failed to make good the promise of its early years.

The early history of medicine in Greece exhibits almost precisely similar features. Alongside

the scientific system based upon the teachings of Hippocrates, there arose another system—the temple system—associated with the deity Asklepios, better known under his Latin name of Æsculapius, at whose shrines, priests, working on the simple faith of the superstitious, practised the basest form of medical jugglery. The followers of Æsculapius and of the Hippocratic school long continued side by side in perhaps too friendly rivalry, but the Greek medical philosophers of the classical period had no worthy successors, and the Æsculapian school eventually gained the upper hand. The active prosecution of anatomical and physiological enquiry gradually fell into desuetude, and, after the death of Galen (A.D. 200), it ceased absolutely. The great classical writings were lost or incarcerated in monasteries. The followers of Æsculapius then everywhere became triumphant, superstitious practices crept in and medicine fell into the hands of priests and charlatans. The priesthood obtained complete control and any attempt to question their authority was followed by penalties affecting this life and the next. Speaking of this period Professor Singer states "Medicine deteriorated into a collection of formulæ, punctuated by incantations, medicine remained surrounded by sacred associations, but the scientific stream, which was its life-blood, was dried up at its source."

The early history of medical science in the East and the West was thus not dissimilar. In both, alongside the scientific spirit which shows itself as a desire, by observation and experiment, by induction and by deduction, to probe into the secrets of nature and to build thereon a rational system of medicine, the followers of another debased system were always prominent and eventually triumphant. The debased system, which in its most primitive form is probably a derivative of nature-worship or Animism, comprises an unreasoned and unreasonable belief in the power of magic and spells. If there is any significant difference between the early history of medicine in the east and in the west, it is that in India demonology was almost from the first given a prominent place, so that the stream of pure science flowing from the spring of Sushruta was early submerged under a debased form of medicine in which astrology and demonic belief played a large part.

To what precise extent the Ayurvedic system was influenced by Greek thought and *vice versa* is not certain, but there is some reason to believe that each borrowed from the other and that the Arabic system, which arose somewhat later, borrowed largely from both. It is, however, probable that the scientific spirit reached a higher state of development in Greece than elsewhere, and we are on sure ground in stating that modern scientific medicine is mainly attributable to the inspiration derived from the writings of the classical medical philosophers of ancient Greece. The point I wish to make here, and it is one of considerable importance, is that no single

country can claim to constitute the birth-place of medical science and that no real distinction and no real rivalry can properly be said to exist, in so far as their early history is concerned, between the so-called eastern or Ayurvedic system and western medicine derived from Grecian sources. In short, the science of medicine is one and indivisible; there are many systems of treatment, but let me emphasise once more there is only one system of medical science and the East and the West each took a share in bringing about its birth.

The dark ages descended in Europe after the death of Galen (A.D. 200) and continued for about 1,200 years. The depraved condition of medical science in England in the 15th Century is well illustrated in the following quotation from the Paston letters (1464), in which Margaret Paston, writing to her husband says:

"Also for Goddys sake be war what medesyns ye take of any fysissians in London; I schal never trust to hem be cause of your fadr and myn onkyl, whose sowlys God asoyle."

There was thus a dark age for science both in the East and in the West, although, as we have shown, it commenced somewhat earlier and was more complete in the East. Here again, we cannot help being struck by the apparent similarity of the happenings in Europe and Asia. Why did the dark ages supervene? Was it an unconscious revolt against an exacting discipline, a mental lassitude, which induced man to bow to authority, rather than to think for himself, or was it disturbances in law and order which brought to the fore the brooding spirit of pagan man? We do not know, but it is difficult to imagine a more fascinating subject or one whose elucidation would more fully repay study.

The next stage in this brief history was the revival of learning and of science which commenced in Europe in the 13th century, but which did not become fully developed until two centuries later. Time does not permit of any account of this great movement which starting in Italy spread through western Europe and eventually in the 18th and 19th centuries to the whole world, and it must suffice to state that during the past four centuries, the progress of medical science, to which all civilized countries have contributed, has been immense and uninterrupted. We can only mention the names of a few of the great medical pioneers, of Leonardo da Vinci of Italy (1452 to 1518); Vessalius of Brussels (1514-1564); Ambroise Paré (1517-1590), the Frenchman, Francostoro (1485-1553), de Baillou (Ballonius) and of Thomas Sydenham (1620-1689) commonly termed "the English Hippocrates."

There was, however, no counterpart in India or in the east of the revival of learning in Europe, and the re-birth of medical science in India may be said to have occurred almost within living memory. There was thus no preceding

latent period during which the spirit of scientific inquiry, at the hands of those I have mentioned and many others, manifested itself despite all the terrors of the law and of the priesthood.

This account of the history of science, though brief and incomplete, does perhaps suffice to enable us to visualise in proper perspective the present position of medical science in India. The dark ages in the East, as we have seen, continued down to almost modern times. Throughout this long period the scientific spirit, so far as medicine is concerned, was dead, and the practice of medicine was, and still largely is, in the hands of Vaidas and Hakims, who, we now see, may be regarded as the lineal descendants of a higher type of practitioner. They are in fact our medical brethren, who, cut off for centuries from observation and experiment, with no knowledge of anatomy and physiology—the sole avenue of approach to scientific medicine—whose botany is a drug list and whose remedies are worthless charms and incantations, have degenerated beyond all recognition. Alongside these men, thanks to the *alumni* of the medical colleges and schools established in India by the British Government, we now have a growing number of medical practitioners trained in the system of which Hippocrates and Sushruta were the founders. But these colleges and schools were originally established to serve the practical purpose of tending the sick, and at first, more especially, to provide for the needs of the civil and military servants of Government. But the practice of a system of medicine does not necessarily mean the acquirement of the scientific spirit upon which it is based. Drugs may come into fashion and disappear, methods of treatment may change, technique may improve, but something more than a knowledge of these things is required if medical science is not once more to degenerate into dead formalism and quackery. The curse of medicine, as of all sciences has always been “the practical man” or the man who considers the immediate end of his art without regard to the knowledge on which it is based. My reading of the situation is that we have at the present time many practitioners but few students of scientific medicine and that, whilst there are some grounds for adopting an optimistic attitude, the future of medical science in India and, in consequence, the well-being of the inhabitants of this great land, is not yet assured. Many of our practitioners have in fact so recently assumed the mantle of Hippocrates and Sushruta, and their contact with the scientific spirit in medical colleges is so brief, that there is a distinct danger of a lapse into quackery. In short, history may repeat itself and what happened at the beginning of the Christian era may occur again in the 20th century. It is for you, by precept and example, to falsify this pessimistic forecast.

Something must be said in regard to the Vaidas and Hakims, those interesting relics, from the historical point of view, of a by-gone age; it is clearly impossible, even if it were practicable,

out of regard for the solace, if not the skill, they bring to perhaps 90 per cent. of the people of this land, to abolish them at once; they obviously must continue until such time as they can be replaced by more worthy and more efficient substitutes. It would of course be folly to bolster up any type of practitioner whose training is unscientific, and every available rupee should be devoted to the provision of medical relief by medical practitioners trained in the methods of the one and indivisible medical science. Let us not waste our time and our energies in discussing the merits or demerits of Vaidas and Hakims. There are, indeed, more quacks inside the medical profession than outside—and the former are much the more dangerous!—but if the Vaidas and Hakims can safely be left to themselves, it is clear that the practitioners of scientific medicine cannot afford to be satisfied with the smattering of medical knowledge they learn as students; they must, in every way open to them, by reading, by contact with those possessing the scientific spirit, by joining scientific societies such as this, and by their every-day professional conduct and practices show their superiority, and thus justify themselves in the eyes of the public. They must, in short, cultivate the scientific spirit and remain students of medicine all their lives. If medical science in India is to advance and not to undergo retrogression—and to my mind the decision is at the moment trembling in the balance—it is essential that close contact should be maintained with all that is best in medical science and that, irrespective of all other considerations, the palm must go to those that deserve it. We must, however, above all, learn to depend on ourselves and I cannot better conclude this lecture than by quoting to you the wise aphorism of Sushruta, so reminiscent of Hippocrates.

“There is no end to the science of medicine. Hence needfully and carefully devote thyself to it, considering it an honour to practise the art.”

Current Topics.

Observations on Chronic Splenomegaly in Childhood: Diagnosis and Treatment.

By. ROBERT HUTCHISON, M.D., F.R.C.P.

(Brit. Med. Journ., August 18, 1928, p. 281.)

BEFORE proceeding to the differential diagnosis of the various splenomegalies of childhood, it is advisable to make sure that the abdominal tumour in question really is an enlarged spleen. Usually this is easy enough, but sometimes one is in doubt, especially as to the possibility that the tumour may be an enlarged left kidney or suprarenal. Sometimes the ordinary diagnostic criteria—that a large spleen does not extend back into the loin, that it has a sharp edge with a notch, that it crosses the middle line below the umbilicus, that the fingers cannot be passed between the tumour and the ribs, that the descending colon does not lie in front of it—all fail, and in that case it is important to remember that dullness extending above the level of the ninth rib in the mid-axillary line is in favour of the tumour being

splenic. An x-ray examination, with pyelography if necessary, may help in the differentiation. I would only repeat that the difficulty of telling a splenic from a renal tumour is sometimes a real one, and that the methods of distinguishing them are worth discussion.

Having settled that the tumour is an enlarged spleen, it is necessary, before proceeding farther, to have some sort of classification of the different varieties of splenomegaly met with in childhood. The only satisfactory classification would be an etiological one, but of that our present knowledge does not allow, and I therefore propose, for purposes of discussion, to consider the subject under certain broad groups.

1. Tumours (Cysts, New Growths, Abscesses, etc.).

These are very rare, and for practical purposes undiagnosable. If diagnosed, the proper treatment, of course, would be surgical.

2. Chronic Infections.

Of these we have to consider Tuberculosis, syphilis, lymphadenoma, and chronic sepsis.

In chronic tuberculosis splenomegaly is not likely to be the "presenting" sign, although in the acuter forms of tuberculosis in young infants enlargement of the spleen is very common. Cases are described, however, though I do not remember to have seen one myself, in which massive cascating tuberculosis leads to considerable splenomegaly. The spleen in such cases may be tender, and polycythæmia and some degree of cyanosis are said sometimes to be present. There will often, of course, be less conspicuous tuberculous lesions elsewhere. The proper treatment is splenectomy.

The relation of congenital syphilis to splenomegaly in childhood is very important, but I would suggest, for purposes of discussion, that its frequency as a factor in causing the condition tends to be exaggerated. After all, inherited syphilis is a comparatively rare disease, and so we may say that, although syphilis certainly very often leads to splenomegaly, yet not many cases of splenomegaly are due to syphilis. It is in infancy that a syphilitic enlargement of the spleen is most likely to be met with, but there is reason to believe that in later childhood—say, between the ages of 5 and 7—splenomegaly may be the only sign of a syphilitic taint, and it appears again about the age of puberty in association with syphilitic cirrhosis of the liver. In the pre-Wassermann days the tendency was to ascribe every splenomegaly of doubtful origin to syphilis, but since the introduction of that test I have been impressed by the frequency with which it is found to be negative in these circumstances. I am aware that in some undoubtedly syphilitic cases—in syphilitic cirrhosis, for instance—the Wassermann reaction may be negative, and we might well discuss what degree of confidence we can place in it as a criterion of the presence or absence of a syphilitic taint. I would only point out that it is, after all, the only positive test we have in a case in which unmistakable objective signs of the disease are wanting, and if we are not to be able to trust it the whole question of the relation of syphilis to splenomegalies of obscure origin in childhood goes back into the melting-pot. It is all the more important that we should have some trustworthy test for the presence of syphilis, inasmuch as it has been suggested by Dr. Parkes Weber and others that an inherited taint may form a basis on which enlargement of the spleen—though not primarily due to syphilis—may develop more easily, or in a more exaggerated degree, than it does in a child whose heredity is not thus burdened. Although this view seems to me rather speculative, it would be of interest to have opinions upon it.

Where syphilis is believed to be the cause of a splenomegaly, vigorous antisymphilitic treatment must, of course, be adopted. In some cases, however, the changes in the spleen may have proceeded so far that they are unaffected by any form of drug treatment, and in that case splenectomy may be justifiable.

Lymphadenoma as a cause of enlargement of the spleen, without there being evidence of the disease in the glands, must be very rare. For my own part, I have

never met with an instance of it, though cases have been described by others, and I do not see how it can be diagnosed with certainty. If diagnosed, the appropriate treatment would be the application of x-rays to the tumour.

Chronic sepsis has been put forward as a cause of splenomegaly, as of most other things. Dr. Gordon Ward, for instance, regards it as of considerable importance, though I think on rather insufficient grounds. That splenomegaly may be the presenting sign in cases of very chronic infective endocarditis (endocarditis lenta) is certain, but I doubt if cases of this very chronic type are ever met with in childhood; and of "intestinal sepsis" as a cause of enlarged spleen we know nothing.

3. Tropical Splenomegalies.

Chronic protozoal infections, as in malaria and kala-azar, may cause great enlargement of the spleen in children, but as the diagnosis and treatment of these diseases is the same as in adults we need not discuss them.

4. Splenomegaly in Metabolic Diseases.

We have here chiefly to discuss the part played by rickets. This has been almost as much disputed as the rôle of syphilis in producing splenomegaly, and, I believe, fully as much exaggerated. That severe rickets tends to be accompanied by some degree of enlargement of the spleen is undeniable, though in some cases the organ is not so much enlarged as pushed down by deformity of the ribs; but I would suggest, for purposes of discussion, that rickets alone is not an important factor in the production of splenomegaly, especially nowadays. The same may be said, with even greater truth, of waxy disease, which we need rarely think of when the nature of an enlarged spleen is under discussion.

5. Gaucher's Disease.

Gaucher's disease should, I suppose, now be included under the metabolic disorders associated with splenomegaly. It is rare, though probably not so rare as is believed, and is to be diagnosed by its familial, though not hereditary, incidence, and, above all, by the demonstration of the characteristic endothelioid cells in the product of a splenic puncture. Opinions as to the value of splenectomy in the Gaucher cases are divergent. The operation cannot certainly be regarded as a cure, seeing that the disease is one which is not confined to the spleen, but affects the whole reticulo-endothelial system throughout the body. If the splenic tumour is causing local discomfort, however, its removal would appear to be justified.

6. Splenomegaly in Diseases of the Blood.

We have here to consider the leukæmias, splenic anæmia of infancy (anæmia pseudo-leukæmica infantum of von Jaksch), acholuric jaundice, purpura, and erythræmia.

The *leukæmias* we may dismiss in a word. In childhood they are almost always acute, and therefore not a cause of chronic splenomegaly. I have only once seen a case of chronic myeloid leukæmia in a child—a boy of 12—and for practical purposes leukæmia as the cause of a chronically enlarged spleen in childhood need not be considered. If suspected, a blood count would at once establish the diagnosis.

The *splenic anæmia of infancy* is in an altogether different category. It used to be relatively common, and when I was giving the Goulstonian Lectures twenty-five years ago I had no difficulty in collecting notes of a large number of cases, all of which had been under my own observation. In recent years, however, it has become rare, and I have not seen a typical case now for a long time. I do not propose to discuss the nature of this disease, and whether it is merely the result of a hæmopoietic reaction to various debilitating influences in childhood, or whether it is—as I at least hold—a disease *sui generis*. For our present purpose it is sufficient to point out that it should not be diagnosed after the age of 3, although it is true that the enlarged spleen may persist beyond that age, when the anæmia has passed off, before gradually disappearing. In that case, however,

there should be a clear history of the disease in the earlier years. The blood picture in the acute phase is characteristic.

In considering the treatment of this form it is to be remembered that the disease tends to spontaneous recovery in the great majority of cases, given suitable hygienic measures. I do not myself consider that splenectomy is ever called for in it, as the operation must be highly dangerous in the severe forms and is unnecessary in the milder. Some successful cases have, however, been reported but I think it probable that these would have recovered without operation. Whether x-ray treatment is of any use I am not sure. In the few cases in which I have tried it the results have been disappointing, but others have been more fortunate. At least, it cannot do any harm.

I need not say much about the splenomegaly of *acholuric jaundice*; it is now well recognized as a not uncommon occurrence, and the diagnosis can be established with certainty from the characteristic increased fragility of the red cells. There is also no doubt that splenectomy is the only effective form of treatment.

In *purpura*—even in the chronic forms—splenomegaly is not likely to be the presenting sign, and I only mention it here because in that variety of the disease in which the platelets are greatly diminished removal of the spleen is now generally agreed to be very beneficial.

I doubt whether true erythraemia (Osler-Vaquez disease) is ever a cause of chronic splenomegaly in childhood, but it is interesting to note that polycythaemia is sometimes a feature in cases of syphilitic splenomegaly.

7. Splenomegaly Associated with Cirrhosis of the Liver.

We now come to that interesting group of cases in which an enlarged spleen is associated with cirrhosis of the liver. Three forms of cirrhosis with splenomegaly—excluding for the moment Banti's disease—may be distinguished.

(a) *Idiopathic Non-alcoholic Progressive Cirrhosis* (Parkes Weber).—This is a cirrhosis of unknown cause, which resembles the ordinary portal cirrhosis of adults, runs a fairly rapid course, and often terminates in hæmatemesis. The spleen is always enlarged to some degree, but in certain of the cases is so conspicuous and early a feature as to be the "presenting" sign, and these have been spoken of as cases of "splenomegalic cirrhosis," or cirrhosis with "splenic predominance." Their diagnosis from Banti's disease is not easy, and will be considered later, and whether or not they are suitable cases for splenectomy demands discussion. Some writers—Thursfield for example—maintain that the operation in these cases is almost invariably fatal, but I am not at all sure that this is true. In the following case, for instance, if, as I believe, it must be included in this group, splenectomy appeared to effect a cure.

The patient was a boy aged 12, who was admitted for bleeding from the gums with a history of always having bruised easily. His spleen was enlarged down to the umbilicus, and the liver was easily palpable. The red cells numbered $4\frac{1}{2}$ million, with 70 per cent. of hæmoglobin, and the white cells 1,600. The Wassermann reaction was negative, both in the patient and in his mother. Four months later he was re-admitted with ascites. The spleen was removed, and at the operation the liver was found to be cirrhotic. Twelve years later he was in excellent health.

The question of splenectomy in these cases is, I repeat, one for discussion.

(b) *Syphilitic Cirrhosis with Splenomegaly*.—These cases are met with in later childhood about the time when interstitial keratitis and the other signs of "late syphilis" manifest themselves, and I have already said that there is reason to believe that they do not always give a positive Wassermann reaction, and that, if anti-syphilitic treatment fails, removal of the spleen may be justified.

(c) *Splenomegaly with Biliary Cirrhosis*.—These are the cases described by Gilbert and Fournier, and are believed to be the form which Hanot's cirrhosis takes in the child. They are said to be characterized by the

presence of a much enlarged spleen, recurring jaundice, finger-clubbing, and impairment of growth, but without ascites. Now I am very sceptical as to the existence of Hanot's cirrhosis at all, and still more sceptical as to the occurrence of such cases in the child. I once thought I had such a case—I have described it elsewhere—but it proved post-mortem to be a case of partial obliteration of the bile ducts, presumably of congenital origin. I shall, however, be interested to hear the opinions of others on the subject.

8. Splenomegaly the Result of Splenic Thrombosis.

That thrombosis of the splenic vein could cause enlargement of the spleen was denied by Osler, yet there seems to be no doubt that it does happen. I have myself seen two cases in the adult in which this was proved at the necropsy to be the cause, and a case of it has been published by Parkes Weber. Wallgren, in an important paper, has drawn attention to it as a cause of splenomegaly in children, and believes that it is commoner than is supposed, but that it has hitherto been confused with Banti's disease. He describes the leading features of the syndrome as splenomegaly, anaemia with leucopenia, and slight ascites. Sooner or later hæmatemesis sets in, and after a bleeding the volume of the spleen *shrinks*—this, he believes, does not happen after hæmatemesis in Banti's disease or in cirrhosis—and at the same time a temporary leucocytosis appears. The liver in all of his cases coming to necropsy was found to be normal.

He is of opinion that the thrombosis of the splenic vein is the result of trauma or of an "infection," and that it leads to engorgement of the spleen and dilatation of the veins at the lower end of the oesophagus, rupture of one of which causes the hæmatemesis, with temporary subsidence of the splenic tumour. Wallgren believes that the prognosis in these cases is bad unless splenectomy is performed.

9. Splenic Anaemia of Adult Type and Banti's Disease.

It will be generally agreed, I think, that "splenic anaemia" and "Banti's disease" are to some extent diagnostic "rag-bags" into which are thrown all the cases of enlarged spleen that cannot be placed in any other category. None the less it will be admitted that cases to which these terms are applicable have a real existence in the adult, and the question for us to-day is whether they are also met with in childhood. Now, seeing that the splenic anaemia of adults is of its essence a very prolonged disease, the final stage of which, when cirrhosis of the liver has supervened (so-called Banti's disease) is only reached after some years, it follows that Banti's disease at least is not likely to be met with whilst the patient is still a child. In spite of this I think the diagnosis "Banti's disease" is sometimes justified in childhood.

The difficulty, of course, is to distinguish such cases from those of idiopathic cirrhosis "with splenic predominance," already referred to. It can only be done if the history shows that the spleen was enlarged for some years (as in the above case) before signs of cirrhosis supervened, for the cases of idiopathic cirrhosis seem to run their whole course in a comparatively short space of time. There is little doubt, too, that cases of splenomegaly due to splenic thrombosis must often have been included under the term "splenic anaemia or Banti's disease," and so, probably, have some syphilitic cases and some of acholuric jaundice.

It is sometimes asserted that the presence of leucopenia puts a case in the category of splenic anaemia rather than of idiopathic cirrhosis, but to this I cannot agree. In the case of idiopathic cirrhosis with splenic predominance which was described earlier in this paper, for instance, leucopenia was present, and my own view is that leucopenia tends to be a feature of most chronic splenomegalies, no matter of what origin, and that little diagnostic value can be assigned to it.

The treatment for splenic anaemia of the adult type, we should all agree, is splenectomy, but whether the operation is worth doing after cirrhosis has supervened—that is, in Banti's disease—is a matter for consideration.

In conclusion, I would suggest as the most important points for us to discuss: (1) the part played by syphilis and rickets in the production of chronic splenomegaly; (2) the nature of idiopathic cirrhosis with "splenic predominance" and its differentiation from Banti's disease; (3) the existence or otherwise of biliary cirrhosis with splenomegaly; (4) the frequency of splenic thrombosis as a cause of enlarged spleen and its diagnosis from other forms of splenomegaly; (5) the occurrence of cases of splenic anaemia of the adult type and its sequel, Banti's disease, in childhood.

As regards treatment, debate must chiefly centre round the question of splenectomy. As to this, I would agree with Dr. Leonard Parsons that the cases suitable for this operation are those which show a negative Wassermann reaction, no enlargement of lymphatic glands, and no characteristic leucocytic picture, but in which there is some degree of anaemia, associated with (1) leucopenia, or (2) increased fragility of the red cells, or (3) hæmatemesis. There may be difference of opinion, however, as to the advisability of removing the spleen in Gaucher's disease and in cases with cirrhosis of the liver, whether of the idiopathic or Banti variety, even although these fall within the limits of the above criteria.

The Therapeutic Value of Valerian.*

By J. S. MANSON, M.D., D.P.H.

(*Brit. Med. Journ.*, Nov. 10, 1928, p. 842.)

I HAVE been greatly impressed with the success of valerian therapy in a large variety of cases of the minor neuroses. The drug was given in the form of the ammoniated tincture of valerian combined with 10-grain doses of potassium bromide. I soon found that the bromide, while adjuvant, was not the essential part of the therapeutic value of the mixture, for if the bromide was given without the valerian the result was less successful or was even a failure. I attributed the action of the valerian to its effect in reinforcing optimistic suggestion through the sense of smell—a psychic rather than a physical or chemical action. Dr. Dan McKenzie, in his book on "aromatics," shows how important is the sense of smell in awakening dormant memories of past experience, and Mr. John H. Kenneth of Edinburgh University had an interesting note in the *British Medical Journal*, 3rd June, 1922 (p. 904), on "osmies and psycho-analysis." Mr. Kenneth thought that osmies—the science of smell—might be of use in psycho-therapeutic practice.

The observations of Mr. Kenneth rather confirmed me in the view that the action of valerian was chiefly psychical. It produced an olfactory stimulus, which in time caused a break up—if I may use the term—of complexes associated with fear and anxiety of external circumstances, or of apprehension of the 'functional' working of the organs of the body—in other words, hypochondriasis.

Further experience in the use of valerian, especially the constant good results obtained when given in the type of case for which it seemed indicated, made me think that valerian had a more definite action due to some chemical factor rather than to an indirect psychical stimulus.

Let me give in general terms the type of case in which I think valerian is indicated. The symptoms usually described are: palpitation, something rising in the throat, flatulent eructations, rumbling of the bowels, sense of pressure on the vertex, desire to be alone, and lack of interest in home and social surroundings, fear of something going to happen, unrestful sleep accompanied by disturbing dreams, lack of mental concentration, and general depression, so marked at times that thoughts of suicide creep into the mind—in other words, the first stage of melancholia.

Women are more affected than men, but I will give an illustrative case which occurred recently in my own practice.

The patient, a man aged 54, was organically sound; he was a confidential clerk in an important firm of solicitors dealing with the administration of large estates. He had nearly all the symptoms described above, and became totally unfit for his work. His firm, appreciative of the value of his services, sent him to a leading consultant, who, after a thorough overhaul, advised a two months' holiday at the seaside, and prescribed glycerophosphates and other so-called nerve tonics to be taken regularly. On his return from his holiday by the seaside he found himself as bad as ever, and could not concentrate on his work.

When he came to see me he described the misery of the seaside holiday. Each vacant day was succeeded by another one, allowing him time to brood over his troubles. I advised him to continue at work, but only to do such work as to maintain his interest, and to avoid the mental fatigue involved in calculations. I gave him the ammoniated tincture of valerian in half-drachm doses and 7½ grains of potassium bromide.

In three weeks his confidence had returned, and after six weeks he could undertake full work involving intense mental concentration in complicated problems of finance. During that period he had taken 12 oz. of the ammoniated tincture of valerian. He has had one or two tendencies to relapse since, but he returns for his smelly mixture to keep him up to the mark.

Similar cases could be cited, but they would be wearisome; suffice it to say that I am convinced that there is enough evidence to show that valerian does contain some definite property which has a decided and specific beneficial action on the higher levels—and perhaps also on the lower—of the central nervous system.

Continental pharmacologists have given more attention to valerian than their British colleagues, but even on the Continent research has been very limited, and the literature, such as it is, is not of recent date. The best account I have been able to find is an article in the *Pharmaceutical Journal* of 19th November, 1921 (p. 402), by Dr. N. Smolaka of the Ministry of Health, Belgrade, entitled "The history and therapeutic properties of valerian." In this article Dr. Smolaka described three experiments on frogs carried out by Professor Wicki at the Pharmacological Institute at Geneva. The frogs were immersed in 1 per cent., 2 per cent., and 3 per cent. solutions of the liquid extract of valerian, and observations made of their behaviour. Dr. Smolaka concludes that his experiments prove that the extract prepared and made by him was of high physiological activity and paralysed the brain of the frog in small concentration. He described the drug as an antispasmodic, because it depressed psychical action.

These experiments on the frog do not help us very much to understand the action of valerian on the human subject; all they do is to show that valerian has a definite action on the nervous system of the frog due to some chemical factor in the drug. It is stated by Cushman that valerian contains borneol, or Borneo camphor, and numerous esters of acetic, formic, and valeric acids. Is it possible that this borneol is the important active principle in valerian?

The action of camphor in depressing the brain and spinal cord is well known, but whether the allied borneol is the valuable active agent is a question to be determined by pharmacologists. All I have tried to show is that valerian is a very valuable drug in general practice, capable of restoring mental efficiency and alleviating mental misery. It has also the advantage of having no deleterious properties such as are associated with the habit-forming narcotic series of drugs. It seems to be a drug well worthy of further research into its properties and action on the nervous system.

A New Test for Pregnancy.

(*Lancet*, October 27, 1928, p. 876.)

ONE of the commonest, and at the same time often one of the most difficult tasks that fall to the lot of the

* A paper read in the Section of Therapeutics and Pharmacology at the Annual Meeting of the British Medical Association at Cardiff, 1928.

medical man is the early diagnosis of pregnancy. There are few conditions which involve such deep-seated and complex changes with so little demonstrable effect. Some recent workers have put forward a test for pregnancy which is founded on a new principle—the presence of certain hormones in much increased amount in the blood and urine during pregnancy, and the demonstration of their presence by simple biological tests. These hormones are those of the ovary and of the anterior lobe of the pituitary. With the ovarian hormone the laboratory worker is now well acquainted; the proof of its isolation and action in promoting the growth of the uterus and bringing about oestrus in castrated female animals is complete. The nature of the anterior pituitary secretion is not yet quite so well defined. Since Picre Marie in 1886 described the condition of acromegaly and observed that the disease was associated with tumours of the pituitary body, the nature of the effect of the anterior lobe on growth has monopolised the attention of scientific workers. Its interrelationship with the ovaries has long been suspected, however, and during the last two years has been strikingly confirmed by B. Zondek and S. Aschheim in Germany and independently by P. E. Smith and E. T. Engle in America. The hormone is supposed to act through the medium of the ovary, in which it brings about rapid growth of the Graafian follicles and in the immature animal may induce a premature oestrus. The work of A. C. Siddall and of Zondek and Aschheim, is based upon the experimental proof of the increase in amount of these hormones in the blood and urine during pregnancy. Siddall's work depends on the presence of ovarian hormone in the blood of the woman whose pregnancy is to be tested. Her serum is injected daily in doses of 1 c.cm. into an immature virgin mouse for six days. On the sixth day the mouse is killed and weighed and the ratio of the weight of the whole mouse to the combined weight of the uterus and ovaries is estimated. If the ratio is less than 400 to 1, the test is regarded as positive. In 142 cases examined nine were erroneous. It is during the early months or weeks of pregnancy that the test would be useful in practice, so that it is noteworthy that in 19 tests on women less than three months pregnant only one erroneous result was recorded. Zondek's test depends on the assumption that the anterior pituitary hormone is the activating factor. It is present in traces in normal urine, but according to Zondek the commencement of pregnancy is quickly followed by an explosive production of anterior pituitary hormone which is excreted in the urine. If samples of the urine from pregnant women are injected into young female mice in suitable doses, and the mice are killed in five days, their ovaries show hæmorrhagic centres and corpora lutea. This phenomenon is said to occur also when an extract obtained directly from the anterior portion of the pituitary gland is injected, but not when urine from males or non-pregnant females is injected. The results obtained by Aschheim using this method, are remarkable. Of 258 control urines examined, four were positive, whereas of 197 specimens of urines from pregnant women only four gave a negative result. The validity must rest upon the confirmation of these experiments by other workers. If some biological test unconnected with the genital system for the presence of anterior pituitary hormone could be devised, the fact that this hormone is the activating substance would be even more clearly demonstrated. The Zondek test is thus of the utmost practical importance and it seems probable that in the near future it may be developed into a standard test which can be carried out with little trouble in any laboratory equipped for biological work, with only a very small chance of error in the results.

Treatment of Asthma in Children with Tuberculin.

By T. M. LING, B.M., OXF.
(*Lancet*, Nov. 10, 1928, p. 972.)

WITHIN the last few years considerable interest has been reawakened in the treatment of asthma with

small doses of tuberculin, the credit for this being due primarily to W. S. van Leeuwen, of Leiden.

Van Leeuwen, working with a large series, claims that about 50 per cent. are almost completely cured, about 25 per cent. are improved, and 25 per cent. are unimproved. Most of the patients so treated have been adults and therefore it was considered to be of interest to try the effect of this treatment on children. Twenty-four asthmatic cases were therefore chosen from the children's out-patient department at St. Thomas's Hospital, all of whom had been receiving treatment for not less than two years, while many of them had had symptoms for a considerably longer time. The treatment that had been given previously was potassium iodide by the mouth and injections of adrenalin during the attacks, while any source of infection in the mouth or nasopharynx had been eradicated.

As a preliminary measure all the cases were examined clinically and radiologically to exclude as far as possible pulmonary fibrosis and enlarged mediastinal glands. Some of the French literature recently has suggested an association between congenital syphilis and asthma and consequently all the cases were examined with this point in view; no suggestive clinical signs were found and the Wassermann reaction was negative in every case. The average age of the patients was 7.5 years.

Cutaneous Pirquet reactions were done in all cases and 45 per cent. gave definitely positive reactions.

Method of Treatment.

In all cases Old Tuberculin (Burroughs Wellcome and Co.) was used and injections were given subcutaneously once a week. As the children were out-patients, it was not feasible to see each case on the day following the injection, but the mothers were instructed to note any general or local reaction that occurred; 385 injections were given and a general reaction was noted in two cases, while a history of a definite local reaction was given in five cases.

The usual procedure was to start injections with 0.1 c.cm. of a dilution of 1 in 1,000,000 and increase the dose on each occasion by 0.1 c.cm. or 0.2 c.cm. until 0.1 c.cm. of a 1 in 100,000 dilution was reached. Beyond this the dose was increased very gradually until the optimum quantity was found for each individual case. When once the correct quantity is obtained, it is not advisable to increase the strength of the injection as an attack of asthma is liable to be brought on. On two occasions this occurred within an hour of the injection, where the strength had been increased unduly quickly.

Two separate courses of treatment have been given with an interval of two months. Naturally the individual attendances were sometimes irregular, but for the whole group it was excellent, and the willingness and enthusiasm with which the mothers brought up the children week after week is probably the best indication of the efficacy of the treatment, particularly as each injection necessitates a certain amount of pain for the child. The average number of injections in the first course was 15 and in the second 10; thus it can be seen that the treatment takes a considerable time.

Results.

Of the original 24 cases, three were unaffected by the treatment and were discharged, while two discontinued treatment as they left the district. The remaining 19 had regular treatment, with occasional weekly lapses owing to intercurrent illness, and are all improved. The word "cure" admittedly should be used with greater caution than usual in asthma and only two cases could be included under this heading. The remaining 15 cases remained practically free from symptoms while under treatment, but lapsed to a varying degree between the course and since treatment was discontinued. In asthma the patient's symptoms are the only index of the severity of an attack, and in every one of these cases the mother was emphatic that the attacks were

much less severe and less prolonged than previous to treatment. A careful record was made in each case of the average interval of freedom from attacks previous to treatment and subsequent to the latter this interval has been increased by approximately 30 per cent.

Conclusions.

Admittedly the results are not striking and do not harmonise with van Leeuwen's claims that 50 per cent. of cases are curable by this means. On the other hand, it is justifiable to state that the frequency and the intensity of the asthmatic attacks can be diminished and this in itself is a justification for a more extended trial and for the inclusion of tuberculin among the methods of treatment of the established disease.

The Idea and the Method in Medical Research.

(*The Journ. Amer. Med. Assoc.*, October 13, 1928, p. 1111.)

CLAUDE BERNARD, in his "Introduction à l'étude de la médecine expérimentale," summed up briefly the relationship between the idea and the method in research:

"The experimental method cannot give new and fruitful ideas to men who have none; it can serve only to guide the ideas of men who have them, to direct their ideas and to develop them so as to get the best possible results. . . . As only what has been sown in the ground will ever grow in it, so nothing will be developed by the experimental method except the ideas submitted to it. The method itself gives birth to nothing. Certain philosophers have made the mistake of according too much power to method along these lines."

In view of the emphasis placed to-day on scientific interest and research in our medical schools, and of the large and increasing numbers of persons engaged in medical research, it appears worth while to restate the relative importance of the idea and the method, with some indication of the contributions to medical knowledge that may be expected from various types of research. To quote Claude Bernard further, "Men with a presentiment of new truths are rare in all the sciences; most men develop and follow the ideas of a few others. . . . We usually give the name of discovery to recognition of a new fact; but I think that the idea connected with the discovered fact is what really constitutes the discovery." Obviously, only a small proportion of those actually engaged in medical research are born investigators; what may be expected, then, from the vast majority in whom training in the methods of investigation is substituted for creative genius? From the majority of them, nothing! Included among these are the large numbers of young men who try their wings and fail to discover a real liking or aptitude for scientific work. Yet their seemingly futile efforts must not be regarded as waste, since from the ranks of the beginners must be drawn the successes as well as the failures. Moreover, no one, however inept, can have first hand contact with the difficulties of advancing knowledge without carrying away with him some appreciation of the scientific method and of the way in which progress is made. The tragedy comes only when the misfit, through bad judgment or advice, continues to go through the motions of research instead of striving for a career in other directions.

From another group may be expected accurate observation, particularly valuable in establishing new facts or in confirming the results of others. Thus every discovery of a new therapeutic method must be subjected to widespread trial and, on the results of such trial, finally accepted or rejected. Much of this trial is quite unscientific, but there are now sufficient numbers of scientifically trained observers to make possible the rapid evaluation of any newly introduced therapeutic method, so that the issue does not remain long in doubt. Many of these observers are clinicians, scientifically

trained, who find time in the busy routine of practice to observe accurately, and their contributions to medical knowledge must not be undervalued.

Still another group, working either in the laboratory or in the clinic, are capable of painstaking contributions by what may be called the analytic method. This method, which is the one employed by the majority of established investigators, varies from the minor set-piece of research, the German *arbeit*, to elaborate investigations having as an object the analysis of natural phenomena, with the hope of resynthesis and complete understanding of the subject under investigation. It may be and usually is employed by the investigator well trained in scientific method but lacking in original ideas, and from the method come many pieces of solid contribution to knowledge. The only danger here lies, as pointed out by Claude Bernard, in attributing too much power to method as a substitute for ideas.

Finally come the favoured few in whom the value of the idea transcends all questions of method. These are the intellects which are so endowed as to perceive and grasp the subtle and delicate relations which exist but of which the average mind is not aware. An idea arises in such a mind which "may be a sort of intuitive anticipation of successful research." From these few, and from these only, may we expect great and strikingly original contributions to medicine. That they must use the methods common to all investigators in establishing the truth of their ideas is of course understood, but the place of method in their lives is distinctly subordinate to the idea—and rightly so!

Dental Disease and Dietetic Deficiency.

By C. F. BADCOCK, L.D.S., R.C.S. (Eng.)

(*The Dental Record*, April, 1928, Vol. XLVIII, p. 186.)

DENTAL caries is classed by Prof. W. D. Halliburton and others under the head of "Deficiency Diseases," and it has been suggested that pyorrhœa alveolaris is also a deficiency disease. Are these diseases of the teeth correctly so described?

I. INTRODUCTORY.

(1) A deficiency disease is a disease of which the definite cause is a deficiency of one or more of the accessory food factors or "vitamins." The class of diseases is in marked contrast to that much greater class associated with a positive agent—chemical poison, pathogenic organism, etc.

The typical deficiency diseases are rickets, scurvy, beri-beri, and pellagra. All these diseases are directly due to the absence of certain indispensable ingredients of a natural diet, and in no way to the presence of micro-organisms or other active irritants.

(2) The known vitamins are: water-soluble B, deprivation of which is the cause of beri-beri, and possibly pellagra; water-soluble C, deprivation of which is the cause of scurvy; fat-soluble A, D and E, deprivation of which is said to induce ophthalmia, rickets, and sterility, respectively.

"Each of the vitamins is essential to nutrition; and each has a special function in the regulation of constructive metabolism."

(3) Vitamins appear to have a catalytic or enzymic action on the functioning of the endocrine glands, and probably on that of the assimilative endothelia. If the organism is deprived of vitamin D the hormone, particularly of the parathyroids, is affected, calcium metabolism in consequence becomes deranged, and, whether or not there is an actual lack of calcium in the dietary, the disease called "rickets" is caused. When rickets occurs, which it generally does, during the time when the tooth germs are being calcified, the calcium content of the blood is insufficient to permit of an adequate supply of calcium salts for this process. The calcifying tooth germs therefore suffer from calcium deficiency, and, correlatively with the under-ossification of bone, become under-calcified or hypoplastic. The hypoplasia or defective development of enamel and

dentine exposes these tissues to putrefaction by micro-organisms, which condition is known as "dental caries."

Rickets indirectly, and calcium deficiency directly, both due to want of vitamins, may thus, by starving the developing enamel and dentine organs of their due supply of calcium, help to deprive the subsequently formed tissues of their natural defence against bacterial attack.

(4) Disease is said to be the reaction of the tissues, or the organism, to injury, but in one's concept of a particular disease the injury itself is usually included.

The causes of disease can generally be classified into predisposing and exciting.

"Predisposing causes are conditions which act upon the living organism so as to render it susceptible to outside agents, and exciting causes are those agents themselves. Thus, starvation may render a person susceptible to attack by a parasitic organism which would otherwise be unable to settle in his tissues and cause disease." (Green's "Pathology.")

We may note that the specific cause of the disease is the particular organism concerned, not the starvation.

It follows that *preventive* treatment is removal of the predisposing cause, while *curative* treatment consists in the removal of the exciting cause and repair of the damage done.

II. DENTAL CARIES.

"Dental caries" is essentially a fermentative disintegration, or putrefaction, of the special calcified dental tissues. This affection of the teeth has retained the unfortunate name "caries" given to it by the older writers; needless to say, it is not analogous to rarefying osteitis.

"Bacteria are the sole initiating cause of dental caries." (J. Leon Williams.)

Unless the dentine be exposed by the loss of its enamel-covering owing to defects in development or to traumatism, dental caries must first attack the enamel, and this is the usual mode of its commencement in a susceptible subject.

Carbohydrate material adhering to, or held in contact with, the enamel surface becomes inoculated with fermentative bacteria present in the oral saliva. The acids (chiefly lactic acid) formed under the protection of the zoogloea films or "bacterial plaques," described by G. V. Black and J. Leon Williams, decalcify the enamel. The zoogloea film serves to protect the organisms from the air and from the cleansing action of the saliva, while permitting the permeation of carbohydrates in solution.

The nascent lactic acid attacks the enamel surface, combining with its calcium salts to form calcium lactate. The interprismatic substance is first dissolved, the rods being detached and rendered friable, and a cavity is formed, by the deepening of which the bacteria obtain access to the dentine. Enamel caries then becomes complicated by the more complex phenomena of dentine caries.

Dentine, unlike enamel, is an organic tissue—less so, however, than bone—having a central cellular medulla (or myelos), the dental pulp, freely supplied with blood-vessels and nerves, and so exhibits *reaction* to the bacterial injury. On the other hand, the dentine tissue offers practically no resistance, and succumbs readily, its decomposition proceeding much more rapidly than that of enamel. The progressive destruction of the dentinal fibrils excites hyperemia in the pulp tissue. The resting odontoblasts are stimulated into renewed activity, the first evidence of which is calcification of the fibrils in advance of the encroaching caries, so obliterating the tubules and forming the "translucent zone." The second stage of odontoblastic activity is the laying down of a coating of secondary or "adventitious" dentine on the wall of the pulp chamber where it has been dangerously thinned. On the further progress of the disease, inflammation of the pulp (odontomyelitis) ensues, and on the bacteria reaching the pulp the inflammation becomes suppurative. We observe, then, in dental caries the necessary factors of a disease; the injury, and the reaction of the tissues—we may also say, the reaction of the organism, as,

consequent on a marked improvement in the general health; the decay is occasionally seen to be arrested in the affected teeth, the denuded translucent zone showing up as a slightly concave facet of considerable extent and hardness, presenting a pigmented and burnished surface. We may, therefore, clearly recognise that the exciting or direct cause of dental caries is the presence of zoogloea masses of bacteria in contact with the enamel and supplied with carbohydrate nutrient material, and that the nature of the disease is a putrefaction of the calcified dental tissues.

There are several circumstances which may predispose to dental caries. These predisposing causes may be divided into two classes, those operating before tooth eruption, and those operating afterwards.

Operating Before Tooth Eruption.

(1) Malnutrition, rickets, and the exanthematous fevers, leading to hypoplasia of enamel and dentine; macroscopic hypoplasia being due to the exanthemata, and microscopic hypoplasia to malnutrition and rickets, and to vitamin and calcium deficiency.

(2) (a) Deficiency of the fat-soluble group of vitamins. This lack of accessory food-factors deprives the parathyroids of the necessary stimulant for the production of their hormone, which is regarded as the chief factor in the regulation of calcium metabolism, and so checks the supply of calcium salts to the developing dental tissues. The calcium content of the blood must be kept at the physiological level, and, if the supply is deficient, this desideratum is effected at the expense of the calcifying tooth germs.

(b) Lack of calcium, magnesium, and phosphorus in the diet.

Clinical experience, in places where special measures have to be taken against infective disease, goes to show that a great deal of infantile rickets, and of dental caries of the deciduous teeth, follows the use of boiled milk for infant feeding, etc., and of boiled drinking water. In the former case the fat-soluble vitamin is destroyed by heat, and in the latter the mineral salts are precipitated, so that the child is deprived of these two most important factors in calcium metabolism. In places where a pure fresh milk and spring water supply cannot be obtained, the pasteurisation of milk and the efficient filtering of water should be employed, or, as an alternative to the latter, a physiological proportion of lime salts added to the boiled water. The danger of infection, especially in tropical countries, is apt to overshadow other considerations, and the simplicity of boiling may become a snare.

The above-mentioned causes must operate some time during the period of development of the dental tissues formed from the tooth germ, i.e., from about the fourth month before birth to about the eighteenth year, and must be effective on the individual teeth before their eruption. They will result in defective development of the calcified tissues, and so predispose these tissues to dental caries.

Operating After Tooth Eruption.

(3) Hypoplasia of the enamel.

The possibility of the re-calcification of the hypoplastic enamel after its exposure in the oral cavity has been mooted. Malleon, Livingston, Cauth, and others, have demonstrated that most enamel (in European teeth, at any rate) is stainable, that is, that there are minute crevices between the rods, presumably where the interprismatic substance is in defect, so that the enamel is permeable. This permeability, they consider, should permit of the adsorption of salt solutions from either the oral or dentinal surfaces into the enamel, and thus of possible progressive calcification after tooth eruption.

There is so far no certain evidence that this ever happens. Molecular changes no doubt take place in enamel as age advances. We note, for instance, that after middle age it gets stained and tends to split. But there can never be a true physiological calcification, such as that of a fibril in the translucent zone of dentine. Whatever "calcification" does occur can only be a crystalloid precipitation of salts in such spaces as are accessible, and such an accretion of inorganic lime would hardly be a protection against dental caries

(4) Vitiating of salivary content.

The crowns of the teeth are, under natural conditions, kept continually moistened at an equable temperature by normal saliva the constitution of which, as Professors Pickerill and Sinn Wallace have shown, is adapted mainly for the protection and preservation of the enamel covering of the teeth. The diastatic action of ptyalin, for instance, is provided not only for nutritional purposes, but, by digesting starches and converting them into substances more easily washed away, to help in rendering the mouth physiologically clean. It is significant that the appearance of ptyalin in the saliva synchronises with the cutting of the first deciduous teeth. Again, the calcium salts of the saliva combine with lactic acid produced by carbohydrate fermentation to form harmless lactates, which are readily washed away. In view of carbohydrate food debris left in the mouth, the free secretion of saliva after a meal is an important aid to leaving the mouth physiologically clean. The conclusion of a meal with fruit or wine contributes to this result. The open-mouth habit, by exposing the front teeth to the air, dries the saliva from their surfaces, so that they are hardly ever bathed in it. Any systemic diathesis or an hygienic habit injuriously affecting the composition or quantity of the saliva will be a predisposing cause of dental caries.

(5) Inadequate detersion.

The non-use of fibrous substances in the food, the use of foodstuffs which do not require thorough mastication, uncleanly habits, and irregularity of the teeth, all encourage the accumulation of nutrient material for bacteria.

III. ALVEOLAR PYORRHOEA.

The tissue susceptible to the disease, pyorrhœa alveolaris, is neither the gum nor the ligamentous periosteum connecting the gum to the bone of the alveolar process, but the ligamentous periosteum connecting the root of the tooth to its socket. The susceptibility of the alveolo-dental periosteum is due to the inherited or acquired effects of disuse, leading to loss of opsonic resistance. By "disuse" is implied a derogation of function below the standard attained during the evolution of the tissue. Alveolar pyorrhœa is a chronic suppurative alveolo-dental periostitis, leading to destruction of the vascular bone of the tooth socket, and collection of the resulting pus in the pocket between the root and the gum formed by the tissue destruction. The cementum of the root is, of course, denuded of its nutritive periosteum, and the tooth is gradually extruded by the ulceration of its attaching tissues as an irritant foreign body. (With other acute and chronic inflammations of the dental periosteum we are not here concerned.)

The causative organisms are the pyogenic streptococci and staphylococci, and probably more or less specific varieties of these which have been evolved in accord with the oral environment.

The chief protection of the dental periosteum against infection from the mouth surface resides in the "gingival organ" and the related ring of lymphoid tissue surrounding the cervix of the tooth. This gingival organ, or "dental tonsil," is an adenoid or lymphoid body, which probably protects the underlying dental periosteum by phagocytosis. When over-worked beyond its functional capacity, like the lingual and pharyngeal tonsils, it suppurates, the gingival pocket corresponding to the open crypts of an ulcerated tonsil (follicular tonsillitis).

The idea that pyorrhœa is a deficiency disease has probably arisen from the similarity of its symptoms to those of scurvy. The manifestations of infantile scurvy in the mouth are very like those of the ulcerative stomatitis so common in badly-nourished children. Ulcerative stomatitis has been shown by Sir K. Goadby to be caused by the same organisms as pyorrhœa in adults, and is undoubtedly predisposed to by dietetic deficiency. It is, however, a disease of childhood, whereas pyorrhœa is a disease of middle and old age. Pyorrhœa is very often seen in those who "live well"; is there any evidence of vitamin deficiency in such

cases? Again, vegetarians take plenty of uncooked vegetables and fresh fruit, and yet seem to be especially liable to pyorrhœa.

Fracture Treatment To-day.

By CHARLES L. SCUDDER, M.D.

(*New York State Journ. Med.*, October 1, 1928, p. 1163.)

I SHOULD like to state certain truths with regard to fracture treatment which are generally recognized as characteristic of treatment as practised to-day.

Progress in the improvement of fracture treatment has been slow necessarily. Surgeons have been uninterested in this subject. The fact that pathological surgery has advanced so rapidly is because pathological surgical diseases killed. Fractures, on the other hand, have only crippled individuals. When it was recognized that fractures did kill, then Lister, following Pasteur's work, reduced the mortality of compound fractures to an almost negligible figure.

That deformity and crippling result from fractures has attracted attention comparatively recently. Because crippling has interfered with the activity of men in industry, a greater interest has been shown in fracture problems than ever before; yet improvement in fracture treatment has been very slow.

With the great increase in motorcycle and automobile accidents, the whole aspect of traumatic surgery has changed. There are more bizarre and unusual types of fractures than ever before. Fracture lines are more likely to enter joint surfaces. Multiple fractures are not uncommon. Frequently important organs are involved. Consequently, the treatment of fractures has become more difficult and it is becoming increasingly so.

Because of the increased difficulty of caring for fractures, we are all coming to recognize the fact that men specially trained for the purpose should take care of fractures of bone. It seems to me that men of a particular temperament and with qualifications which do not often exist in the present-day general surgeon should be trained for this special work. The industrial and traumatic surgeon is of a very different type from that of the older more general surgeon.

The general practitioner will always care for many fractures and certainly may and can care properly for many of the simple fractures. This will always be true. The important fact is that he should recognize the cases which are difficult for him to take care of. If the man in general practice, whether it be in surgery or medicine, who has a general knowledge only of traumatic lesions, would call in consultation at an early date someone understanding better than he the proper care of fractures, many of the terrible results which are now seen would be eliminated. An early consultation, within the first twenty-four hours of the injury, is imperative if fracture treatment is to improve. To delay a consultation for a week or ten days is harmful and may be a cause of many complications arising so that the case which was simple at first becomes very complicated.

It is possible for the general practitioner in all cases of injury to the extremities to give the initial treatment which the fracture requires in an appropriate and simple manner. No fracture of the upper extremity or of the lower extremity need be badly treated if every general practitioner understands the application of and properly applies the Thomas splint for the upper and lower extremities.

All fractures should be regarded as emergency cases. A case of appendicitis is treated at once. Cases of extruterine pregnancy, cases of perforated duodenal ulcer, cases of mesenteric thrombosis, are all regarded as emergencies and treated as such. I believe that every fracture should be treated instantly, both in private practice and in hospital practice. With the immediate proper treatment of a fracture, local swelling is almost always eliminated, shock is diminished, the

fracture will be easier of reduction, time will be saved to the patient, as well as suffering. Moreover, the early treatment will determine, if it is ineffective, the necessity for an operation.

A fracture is damage to a very complex mechanism. The will of the individual patient is affected in every fracture. It is important to secure the co-operation of the individual who is injured in the care of the fracture and during the prolonged convalescence.

There is prevalent a new conception of bone, for which I think we are indebted mostly to Dr. Neuhoff. Bone is no longer an inert, dry, stable form of matter. Bone is a living tissue; it has to do with the vital processes of the body. Bone not only maintains the form of the body and serves as a means of locomotion, but it is a reservoir of calcium and is intimately related with the metabolic processes. When bone is damaged, the reaction to that damage is seen in the reparative processes which bring about union. Recognizing how delicate a tissue bone is, we understand why it is important to handle a fracture with gentleness; in other words, in the examination of a patient with fracture, it is important to avoid undue traumatization of the site of the fracture by rough manipulation. During the progress of the healing of a fracture, it is unwise to make repeated examinations to determine whether union is present. The rough handling and the frequent manipulations tend to hinder the reparative process and may even be a factor in a delayed union.

It is important that we know something of the results of our fracture treatment. Very few of us are able because of a careful study of end results of even small groups of our individual cases, to state what these results are. We do not know whether the kind of treatment that we are using is really the best treatment because we have never studied the final results.

In the treatment of fractures we have a non-operative method, based upon certain principles and employing a variety of methods, that is, traction, counter-traction and manipulation. We have also the operative method, based upon certain principles which underlie all operative procedures. By the operative method, we attempt, by direct re-position, to influence the fracture.

There is no doubt that we are beginning to understand and recognize when skin traction is inadequate. I believe that this marks a distinct step ahead in the traction treatment of fractures of the shafts of the long bones. We see in a given type of fracture that it is impossible to reduce it by traction applied to the skin surfaces because the force necessary to pull the bones apart causes a slipping of the adhesive plaster and results, in inadequate application of the force used. Therefore, recognizing, through our study of the type of fracture, this fact of the inadequacy of skin traction, leads us at the outset to employ the alternative and more efficient skeletal traction.

I believe that we are able to-day, as a result of experience, to state that the operative treatment in a limited group of cases is the best initial treatment. This, too, marks a distinct step in the progress of fracture treatment. It is needless to say before this audience that the operative method must be used only by those who are skilled in its use and under proper indications.

There is no general fund of surgical knowledge regarding fractures which permeates the profession, such as exists in connection with pathological surgery. A person has an attack of appendicitis. Instantly the professional man in charge of that case reacts to what should be done. In connection with fractures, the situation is hazy and there are doubt and uncertainty as to the immediate steps to be taken. I believe that with the improvement in fracture treatment with an increased knowledge of the results of fracture treatment, there will come a time when there will be general information throughout the profession as to the wise thing to be done at the outset in every fracture case. When this time arrives, the ideal treatment will be the initial treatment and the initial treatment will become the ideal treatment which may be contained throughout the whole course of the case.

The deeper one goes into any particular problem the more important that problem seems to be to the individual. I believe that to-day there is no problem in the whole of surgery more important than this subject of the treatment of fractures. There is a demand for a higher standard of result following a fracture than ever before. The economic importance of a fracture is coming to be understood and recognized. We are judging of the results of fracture treatment by the restoration of the function of the part injured. These three facts are so new that the whole subject of traumatic surgery assumes an importance which a few years ago would have been unbelievable.

And finally, I believe that the recognition of the importance of securing good function is illustrated by the fact that in injuries near to joints, the prolonged immobilization has been done away with and we see an early active guided movement employed, securing for the patient greater joint movement, rather than the stiffness and disability which formerly resulted.

I have thus stated briefly those truths regarding fracture treatment to-day which appear to characterize this treatment as an improvement over that employed a few years ago.

Proposals for Next Steps in Preventive Medicine and Public Health.

By LOUIS I. HARRIS, M.D.

(*The Journ. Amer. Med. Assoc.*, August 25, 1928, p. 529.)

THE COMMUNITY FAILS TO DEFEND ITSELF.

In various parts of the country, certain groups have organized to oppose fundamental activities in the practice of medicine especially as they relate to the prevention of disease and to research work, or they have sought to legalize cults and fads whose practices, if unrestrained, would seriously jeopardize the public welfare. Time and again, state and county medical society representatives have had to appear before legislative bodies and other assemblies to defend the community against efforts to scrap those phases of preventive medical service which have contributed in a substantial and even to a remarkable degree to minimize or even eradicate diseases such as smallpox, diphtheria, typhoid, and rabies.

These efforts to legalize the practice of bizarre and fantastic cults and methods of treatment, and to secure for their "practitioners" the standing of medical practitioners without the benefit of a fundamental medical education, have engaged the efforts of many public spirited scientists in the medical or allied professions.

As soon as one cult is successful, a new group that wishes to exploit a variant of massage or of some "drugless" method of healing arises and clamours for legal recognition.

The eyes of the public have been opened in some degree to the dangers of diploma mills, and efforts to suppress this type of fraud have been supported. We are, however, constantly confronted by those who find diploma mills closed and being therefore unable to achieve a medical diploma by the easy expedient of buying a diploma from mill operators, they then claim that scientific medicine is fallacious and unsound and that they are the originators or the disciples of a new school of teaching, be its claims ever so fantastic and impossible. These groups employ lobbyists and resort to every political and publicity device to help them secure a legal status as medical practitioners.

There have been endless encounters between the medical profession and the lobbyists for the chiropractors, the naturopaths and many other groups who seek a short cut to the title "doctor" and who eschew medical education, seeking commercial profit by serving as "healers" of one kind or another. As a participant in many such conflicts before state legislators, I have come to feel that the situation is anomalous. The medical profession has lost neither prestige nor opportunities for service, no matter how many

cults have been allowed to practice in any community, nor how great the number of medical pretenders may have been.

I have joined in the defence of the public health when efforts were being made to strip the health officials of their legal right to employ measures which scientific experience had proved to be invaluable in the prevention of disease. The thought has obtruded itself again and again that the medical profession should not bear the brunt of the burden to defend a community against exploitation. The medical profession would of course under no circumstances withhold its aid, or be passive in the face of resistance to the progress of preventive medical science.

It has appeared signally strange that we have not before this brought it home to those who are the leaders of thought in every community that the burden of protecting the community devolves in equal measure on every intelligent and sane person who has the well being of his fellows at heart. The time has come when, ignoring the insane, fanatical or mercenary fringe who seek to exploit the credulous or the psychopaths, we ought to make it clear to every community that it can have only such public health protection as it is willing to fight for. The defence ought not to depend on the medical profession alone.

The cause of public health will be tremendously promoted if physicians serve notice on the influential and well balanced editors, pulpit occupants, leaders of women's clubs, merchant and trade associations, and civic organizations of our respective communities generally, that, in the future, the medical profession will not be subjected to the charge that it is a medical trust seeking to bar out competition, when in reality its effort is to protect the community from pretenders, frauds, charlatans and quacks of all kinds and degree who would mercilessly exploit the public.

When legislation is proposed that threatens the public health, there ought to be a strong and compact organization of those civic groups in the community whose education and civic spirit make them the proper leaders of the public, and they ought to rise and lead in opposing any efforts that threaten the public health. The medical profession should join such groups to make available the scientific facts and knowledge that have been gleaned during the comparatively short period of development of what may truly be termed scientific medicine.

Physicians who stand aloof from Public Health.

We must not express too great impatience or be too harsh in our judgment if the community as a whole has failed to shoulder the burden of protecting the public health, because we find not infrequently that physicians draw away in a certain haughty aloofness from interest of participation in public health work. Time and again it has been the experience of those physicians who have chosen public health as a career to discover among their confrères a certain air of condescension if not of utter disdain for public health work and those who carry it on. I have frequently encountered physicians who make no disguise of their indifference to public health. Not infrequently a physician has written that he is not interested in this or that public health enterprise on the peculiar ground that he is a surgeon or some type of specialist. What can be expected of the laity, if physicians will not manifest interest in public health? If the practice of a speciality in medicine becomes so narrowing in its influence, it is either a reflection on the excessive lengths to which specialism has gone or else is clear evidence that the physician who disclaims an interest in public health is merely a high grade mechanic. He has not the quality of mind or heart that entitles him to call himself a physician with all that the term connotes by reason both of tradition and of the general expectation that the physician shall of all groups be distinguished for his desire to avert disease and death so far as possible, and to reduce the need for curative work to the lowest possible degree by promoting methods for the prevention of sickness.

Colleges and Hospitals in relation to Public Health.

It would be most desirable if health centres were conducted by health departments at medical schools as a co-operative effort for purposes of teaching. Students will never acquire a wholesome respect for public health work and be its active allies unless they serve an apprenticeship in field and clinical work in relation to public health and learn from experience how certain preventable diseases can be prevented.

This will make for the mobilization of all health and medical services into as few units as possible, or, to put it differently, it will prevent their dispersion. The hospitals are too frequently merely casualty stations. They ought to serve as health centres as well, and provide facilities for the conduct of the varied types of treatment and service that are now familiar public health functions.

Industrial Hygiene, the Cretin of Public Health Medicine.

In spite of our tremendous advances in industrial development throughout the country, there has been comparatively little growth in industrial hygiene as distinguished from what is essentially first aid service in industry. There are a few noteworthy exceptions. Of intensive work in industrial hygiene conducted by municipal health departments, there is little or no evidence.

Reviews.

BLOOD-PRESSURE: ITS CLINICAL APPLICATIONS.

—By G. W. Norris, A.B., M.D., H. C. Bazett, M.B., B.Ch., F.R.C.S. (Eng.); and T. M. McMillan, A.B., M.D. 4th Edition. London: Henry Kimpton. 1928. Pp. VIII plus 387 with 47 engravings and 1 coloured plate. Price 21s. net.

ENCOURAGED by the cordial reception accorded to the first three editions and in view of the appearance of important literature on the subject, the authors have brought out the fourth edition of their book on "blood pressure; its clinical applications." The book, the authors point out in the preface, has been considerably rewritten and the chapters dealing with physiology are entirely new. The chapters on physiological considerations give an excellent summary of the physiological aspects of the problem of circulation and give adequate attention to the capillary and venous pressures, embodying the recent researches on the subject. The methods of instrumental measurement of blood-pressure in arteries, veins and capillaries are given in detail. Tests to determine functional efficiency of circulation like Crampton's test, Schneider's test, Barringer's test, will prove of value to the clinician. Chapters on hypotension and on blood-pressure in infectious disease are interesting and enable one to understand these conditions fully and to appreciate the line of treatment to be adopted. Arterial hypertension is fully dealt with and the general and medicinal treatment of this important pathological condition is thoroughly discussed. Three chapters are devoted to the study of blood-pressure in cardiac diseases, in arteriosclerosis and to blood-pressure in relation to endocrine glands, etc. The study of blood-pressure in surgery, in diseases of the central nervous system, in obstetrics and in ophthalmology are specially contributed to by experts on these subjects and are very interesting and instructive.

The book is valuable from both the physiological and clinical points of view and gives a clear picture to the clinician of the circulatory changes that occur in the body in various conditions that he is called upon to treat. Reference made to the treatment of various pathological conditions will no doubt be of great use to the clinician.

R. N. C.

PATHOLOGICAL PHYSIOLOGY OF INTERNAL DISEASES. Functional Pathology.—By Ablon Walter Hewlett, M.A., M.D., B.S. Revised Edition. 1928. New York & London: D. Appleton and Co., Pp. 787 with 164 illustrations. Available from Butterworth & Co., Calcutta. Price Rs. 26-4 net.

THIS, the third edition of this comprehensive book dealing with the changes in the functions presented by patients suffering from internal diseases, is very welcome. Although the plans for complete revision were outlined by Dr. Hewlett himself, owing to his untimely death, this work had to be carried out by a board composed of a number of his colleagues. The revision of a book like this is a difficult task as it involves a systematic consideration of all the recent advances in the different realms of applied physiology, biochemistry, immunology, hæmatology and clinical medicine. The revising board have, however, done justice to all these subjects as presented in the book and the physician gets an insight into various physiological concepts which are so essential to the rational interpretation of symptomatology in modern medicine. The chapter on the dynamics of the heart muscle is fairly lucid but in places the subject-matter appears to be summarily dealt with. The study of capillaries has not received proper attention, and in view of the fact that a lot of work is done on the vitamins this subject might have received fuller consideration. The chapter on metabolism, especially the section on acid-base equilibrium, is very instructive. The chapter on pernicious anemia summarises the confusing and rapidly growing literature on the subject. The chapters on hæmatology and immunology are very comprehensive; although the recent conceptions about the pituitary and gonads have not been included, the chapter on endocrinology, on the whole, is worth reading. The bibliography appended at the end of each chapter needs special mention. The references are mainly collected from English books and periodicals and ought to be most useful to the English-reading population.

R. N. C.

LABORATORY DIAGNOSIS AND EXPERIMENTAL METHODS IN TUBERCULOSIS.—By Henry Stuart Willis. London: Baillière, Tindall and Cox. 1928. Pp. XXV plus 330 with 25 figures in the text. Price 16s. net.

THIS well-illustrated book is written by an author with considerable laboratory experience in tuberculosis. The aims of the book are twofold, to describe some of the more important methods of the laboratory diagnosis of tuberculosis and to consider some of the more significant procedures and principles involved in the experimental study of the infection.

The first chapter gives a useful description of the various exudates and transudates found in tuberculosis and the methods of obtaining and examining them. The demonstration of tubercle bacilli by staining is fully discussed in the second, and in the two following chapters the discovery of bacilli by concentration and animal inoculation are described. Thereafter the bacillus itself and the various culture media used for its growth are dealt with.

In the third part of the volume, diagnosis by tuberculin is discussed and in the fourth tuberculo-complement and other serological tests are dealt with.

The fifth part is devoted to the inoculation of animals with the tubercle bacillus. In this section there is a useful description of anatomical methods for the injection of animals with coloured injection masses, and vital staining is described; there are also a few statements concerning allergy and immunity to tuberculosis.

The description of histological technique in the fifteenth chapter is excellent and the book ends with a list of equipment for a tuberculosis laboratory and a very complete bibliography.

The style is lucid and abstruse parts of the subject are made easy to understand. There are many practical hints which will be found useful even by those working on other diseases besides tuberculosis.

For the thorough understanding of the laboratory side of tuberculosis, no better book could be

recommended to the medical practitioner or student and it will be found a useful work of the reference on the bookshelf of the experimental laboratory.

The following quotation from the introduction by another worker at the Johns Hopkins University well describes the scope of the book:—"It is not to be doubted that we have now passed the time when the needs of the worker, interested with any of the myriad facets of tuberculosis, can be best served by a multitude of unrelated sketches and references scattered over and throughout a terrain that is as long and broad as the multipartite divisions of modern medicine. A germ that habitually bears down upon almost every organ and tissue of the body necessarily creates a corpus of diagnostic method that is commensurate with the unrivalled multiplicity of its pathological and clinical manifestations. The works on urology will present their share of the diagnostic procedures of tuberculosis, the works on orthopedics theirs, on gastro-enterology theirs, and so on; until to-day the laboratory diagnosis of the infection can be got at only in discouragingly piecemeal fashion by practitioner, student, or professional technician. For bringing together within a single volume these numerous diversified methods and for appraising them to the enlightenment and profit of the unspecialized worker, Doctor Willis deserves the thanks of the medical profession."

E. M.

VARICOSE VEINS.—By Ronald Thornhill, M.B., Ch.B. London: Baillière, Tindall and Cox. 1929. Pp. XI plus 63 with 1 figure. Price 5s. net.

THIS book deals with varicose veins "and their treatment by *empty vein* injection." It is one of the many replies which are constantly being made to those unthinking people with cramped intelligence, who say that it is not likely that any essential advance will be made in treatment by medical men when it is to the patient's advantage and their own disadvantage! Sir Berkeley Moynihan in a foreword states that "a new, simple, safe, quick device has been found for dealing with conditions formerly remediable only by extensive and protracted methods."

The author speaks from a large experience, and discusses in successive chapters the etiology and pathology of varicose veins and the details of the injection treatment. The quinine urethane injections are usually employed, but it is probable that even better chemical solutions than this will be discovered. Many thousands of cases have now been treated, so that the method is based on a satisfactory foundation; above all its safety is assured, for cases of embolism are almost unknown.

Medical practitioners will welcome this small book as a guide to a new and efficient method of treatment for a condition which may be distressing and difficult to deal with by operative procedures.

F. P. C.

RESEARCHES IN POLYNESIA AND MELANESIA. PARTS V—VII.—By P. A. Buxton, M.R.C.S., D.T.M. & H. Published by the London School of Hygiene and Tropical Medicine. 1928. Pp. XI plus 139 illustrated. Price. 9s. net.

"RESEARCHES in Polynesia and Melanesia" embodies the results of the investigations in Samoa, Tonga, the Ellice Group and the New Hebrides in the years 1924, 1925; and parts V—VII under Professor Buxton's authorship are got up together in a neat volume of 139 pages with 27 text figures—No. 2 of the memoir series of the London School of Hygiene and Tropical Medicine.

Part V of the volume which is devoted to studies in filariasis is divided into the following sub-divisions: (a) Methods, (b) Normals, (c) Pathological conditions, (d) Filariasis in Oceania, and (e) Summary. In the "Foreword" the author explains that though according to their original programme the study of filariasis was not intended, a stay of some months in the Samoan islands impressed on him the necessity to devote some attention to that disease and that filariasis is discussed in the book in relation to the other work done in Oceania.

As for the methods of study, to quote the author's own words "my general plan was to examine as many males of all ages as possible; to take a sample of blood from each; and at the same time to record the presence of certain physical signs. In doing this, standardised methods were employed, and the greatest care was taken to develop and retain a uniform technique."

Normals.—The previous studies by Bahr and O'Connor of the state of filarial incidence in the normal population were more of a qualitative than of a thorough nature. So a detailed study of the prevalence of the disease in males was undertaken and through the co-operation of the head men of the village, the District Officer and the native medical practitioner, valuable data were collected from the male population as "even in Samoa the women were less approachable than men and in the New Hebrides, where microfilaria is nocturnal, the pursuit of women at night may be dangerous as well as hopeless!"

In spite of the fact that the highest percentage examined was under 16 years of age, it is significant to note that up to the 15th year incidence among the population is comparatively low, and the author observes that the microfilaria is not found in early childhood in those parts of Oceania which have been studied and discusses the importance of these figures in the light of conflicting records obtained in other parts of the tropics. After a brief description of the physical signs of manifestation, co-efficients of correlation are worked out for several interesting features which are finally followed by a narration of the microfilarial count.

Pathological Conditions.—In his introductory note in the chapter on pathological conditions the author observes "we accumulated a relatively large mass of facts about certain aspects of filariasis and I think that our observations contribute to the solution of the problems of that disease. I therefore feel compelled to tabulate and publish these data. I shall confine myself to these aspects of the disease on which I have something new to say."

"Myositis," "Hydroceles," "Elephantiasis," and "Other Clinical Observations" are the broad divisions into which the pathological conditions are divided, and under each information such as incidence, clinical facts, pathological notes, causes, etc., are discussed on copious data. From the material collected, the author is inclined to the view that myositis in Oceania is a separate disease and that it is not a sequela of filarial infection; that in hydroceles traumatic cases do not fall in a class by themselves and that they ought to be regarded as filarial cases with an added element of trauma; that in elephantiasis, though *filaria* is an essential antecedent, its exact relation to elephantiasis is not known; and that it seems certain that nephritis is not a sequel of filariasis in Samoa. A detailed discussion of this very interesting chapter will be out of proportion to the scope of this review, but we shall content ourselves by drawing the special attention of the workers on the subject to the various original views—views based on observed facts—placed before the reader.

The chapter on Filariasis in Oceania is a clear analysis of the state of prevalence of the disease and its distribution. In a four-page summary the results of the observation are all beautifully epitomised.

Part VI of the book is devoted to a very brief survey of the distribution of diseases other than filariasis for example yaws and syphilis, tuberculosis, enteritis and dysentery, gonorrhoea, leprosy, tetanus, exanthemata, diseases of the eye, intestinal helminthiasis, neoplasms, spleen rate and abnormalities; and the last chapter on "Brown man and White" in Samoa, in which the author compares in a charming style "this picture and that," namely, the inhabitants before and after the introduction of western civilisation, is more or less of anthropological interest.

The memoir forms a valuable addition to the study of diseases in the tropics and deserves the serious attention of workers interested in tropical diseases. We

welcome its publication and warmly commend it to our readers.

S. S. R.

TAKING THE DOCTOR'S PULSE, AND ANOTHER ESSAY.—By J. F. Montague, M.B., F.A.C.S., Philadelphia and London: J. B. Lippincott Company, 1928. Pp. 103. For private distribution. Nominal Price \$1.00.

THE object of the two essays contained in this book is to advocate a more extended use of the cinematograph film in medical education. That the motion picture can play an important rôle not only in the education of the medical man (or potential medical man), but also in the instruction of the non-medical public, is unquestioned; indeed it has already been co-opted as a valuable ally in the realms of embryology, pathology (especially in connection with tissue-culture work), and, most of all, public health propaganda. But when Dr. Montague suggests that practical work in anatomy and in physiology should be replaced by cinema demonstrations of these subjects we cannot agree. The medical curriculum in these days is hopelessly overcrowded, and the author's plea for a shortening of the time devoted to fundamentals and the utilisation of the time thus saved to work in the hospital ward and out-patient department will meet with unqualified approval, but medicine is essentially a practical subject and any saving of time should not be effected at the expense of practical work at any stage of the curriculum.

The suggestion that the cinema-camera might be profitably employed in the operating theatre is worth consideration. We feel certain, however, that there are some surgeons—lamentably deficient "forward-lookers" no doubt—who would pugnaciously resent the suggestion that their activities in the holy of holies should be to some extent controlled by a camera-man, complete with eye-shade, horn-rims and possibly megaphone, and suspended Icarus-like above the field of operation. The purist might find scope for criticism of the author's style. "Thru" and "thoro" are strange to English eyes but they are doubtless good American, "obligated" is common in legal phraseology, but not in every-day speech—at least in English-speaking countries, "to we of the medical profession" is wrong—on both sides of the Atlantic, "ther" for "their" (p. 28) is probably a printing error, while "listening to the ballyhoo of an operator" is, one gathers, distasteful to Dr. Montague, and also, let it be said, to the reviewer.

At one point the author shoots off at an amazing tangent with the suggestion that men of mark in other spheres of activity, instead of retiring from active work at 50 or 60 "should transplant the intellect which has made them industrial giants to the field of medical research." Is it possible that the author does not know his Osler?

The major criticism that we have to offer does not concern the two essays themselves, but the remainder of the book. The essays mentioned occupy a total of 44 out of 103 pages; the remaining 59 pages are devoted to brief synopses of three other books by the same author complete with prefaces, tables of contents, and extracts from the reviews of various British and American journals. This practice—undoubtedly borrowed from the picture theatre—is uncommon in medical books and, in our opinion, should not be widely imitated.

The price, though "normal," presumably has to be paid in hard cash, and we feel that the reading of Dr. Montague's essay at the rate of an anna a page is a luxury that few of the medical practitioners of India can afford.

CLINICAL OBSERVATIONS ON INFANT FEEDING AND NUTRITION.—By H. B. Gladstone, M.D. (Edn.). London: William Heinemann (Medical Books) Ltd. 1928. Pp. XII plus 118. Price 7s. 6d. net.

GLADSTONE'S "Clinical Observations on Infant Feeding and Nutrition" is written by a general practitioner

for general practitioners, welfare workers, nurses and mothers. It is well written and the teaching is sound and well considered. No special line of feeding is recommended: the dried milks are given a high place, after breast milk, in the first three months of infant life. The composition and methods of preparing the various foods are fully described.

The difficulties and disorders of infant feeding are superficially dealt with and the remedies indicated. There is a good account of the vitamins, and some pages are devoted to actinotherapy.

One or two statements are vague and without proof, e.g., "The element of freshness is necessary to stimulate normal digestion and metabolism." One wonders what is the "element of freshness" apart from the vitamin content. Maltose or dextrin maltose is said to be the most quickly absorbed of all carbohydrates: what is the proof of this?

The book is excellently printed. Although there are other and better books on the subject, the author is to be congratulated on his work which can be recommended to those for whom it is intended.

S. A. McS.

IDEAL MARRIAGE: ITS PHYSIOLOGY AND TECHNIQUE.—By Th. H. van de Velde, M.D. Translated by Stella Browne. London: William Heinemann (Medical Books) Ltd. 1928. 323 pp. with 8 colour plates and 4 graphs. Price 25s. net.

THIS is not an easy book to review. A generation ago the medical practitioner knew little or nothing of "sexology"; it was not included in his medical curriculum and the reviewer can speak from personal experience, as a civil surgeon in India, of the embarrassment which he felt when consulted on such intimate details by young married couples. To-day, the circle has turned full wheel, and books dealing with birth control and contraceptives are so common-place that they tend to become rather boring.

The volume under review, however, is something entirely different. In the introduction by Dr. J. Johnston Abraham, C.B.E., D.S.O., M.D., the latter writer states that "this is the book on the physical problems of marriage we have all been waiting for. It had to be written; and written exactly in this way—soberly, scientifically, completely, without a scintilla of eroticism, and yet with a sustained note of high idealism..... In this book will be found all the data bearing upon the physiology and technique of sexual congress, clearly stated, without pruriency or mock modesty—in other words, scientifically." With this summary we are in complete accord. The author is a man of fifty years of age, for many years formerly Director of the Gynaecological Clinic at Haarlem, and the author of many papers and publications in obstetrics, gynaecology, and bacteriology. The very difficult subject treated is handled scientifically, without eroticism, and yet in very plain terms.

The book is divided into four parts. Part I deals with the general physiology of sex. Here there are fully considered marriage as it is—actual and ideal; the stimuli involved in sex impulses—both direct and indirect; and the rôle of the associated senses in arousing sexual impulses. Part II deals with the anatomy and physiology of sex, is illustrated by the colour plates at the end of the volume, and covers ground more or less familiar in such works.

Part III, however, is that which differs so fundamentally from the treatment of the subject in other books which deal with it. Here we have very fully stated in plain terms, but in strictly scientific language, the entire technique of sexual intercourse, from the erotic kiss to the final orgasm. It is this part of the book that may well arouse criticism; yet we believe that the author has a very definite purpose to fulfil and that the sexual lore imparted in these pages will appeal to two classes of readers—the medical man who may often be consulted upon the subject, and who is often very ignorant of it; and the recently married husband, whose ignorance is still more profound. Writing as a married man of more than twenty years'

standing, the reviewer considers that this part of the book would help innumerable couples to make marriage a much happier business than it is wont to be. The author is emphatic on one aspect of marriage; the bride must be wooed as much and even more after marriage than before; the sexual impulses generated in the female partner must be gratified, and only when the husband has educated his partner fully is sexual intercourse fruitful, and desired, and not resisted by the wife.

That this is true is a fact which almost every member of the medical profession probably knows from personal experience of the practice of his profession. The crude bachelor's idea that the nuptial night is an orgy of indulgence on the part of the husband, and the honeymoon a prolongation of eroticism on the part of the male partner, is nonsense, as every married man should know. There is no period of married life when more consideration and more inhibition is called for; the female partner must be educated, taught, considered—at every step. And Dr. van de Velde's writing is plain speaking itself. He describes the preliminaries to sexual intercourse very fully, and details eleven positions for coitus, with a table to show the different types of persons of both sexes to which they are applicable. Graphs are given which present in graphic form the sensations of both partners in different types of intercourse. In common with most medical experience he condemns "coitus interruptus" unreservedly; it leaves the female partner with her erotic impulses fully aroused but ungratified, and with resulting pelvic congestion lasting for hours after the act. Even the after-effects of coitus are considered.

In Part IV, the bodily, psychic, emotional and mental hygiene of intercourse are considered; and again the advice given is sane, sound, and practical. A feature of the book is its "intermezzos" of aphorisms—ancient and modern—with regard to the art of love; there is here much that is both witty and apposite.

Present-day marriage is an utterly blind business. The two partners suddenly drive into it with little or no pre-knowledge, or premeditation. The result is too often the sequel of repulsion on the part of the wife, unfaithfulness on the part of one or both partners, mutual dissatisfaction, and—finally—the divorce court. Dr. van de Velde's main thesis is that this is preventable; but it is necessary that the husband should realise that "marriage is a science," that the female partner has to be initiated and educated in the fullest senses of the terms, with the utmost consideration and care. That thesis we believe to be a very true one, but it is by no means as yet universally realised. The medical man is not infrequently consulted by patients of both sexes with regard to such intimate matters, and—in the terms of Dr. Johnston Abraham, who writes the introduction—we believe that "this is a book that should be in the library of every doctor, who looks upon his patients not as 'cases,' but as human, very human beings entrusted to his care."

APPENDICITIS.—By H. A. Royster, A.B., M.D. New York and London: D. Appleton and Co. 1927. Pp. 370 with two coloured plates and 65 figures in the text. Price 21s. Available from Messrs. Butterworth and Co., Calcutta. Price Rs. 15-12.

APPENDICITIS is such a common disease in the general practitioner's work that any monograph which will further its scientific understanding will always be appreciated in spite of the many books, articles and journals that have already been written on the subject.

The author has reviewed the important papers dealing with inflammation of the appendix for the last 5 years and has given his own views and the opinions of others on our present knowledge concerning appendicitis. The monograph opens with "last words" on appendicitis by such giants in the art of surgery as Murphy, Ochsner, Deaver, and Mayo. Chapter I, deals with an historical sketch of the disease. It is of interest to know that anatomically the appendix has been known since the 16th century, pathologically recognised in the

18th century and clinically is the product of the 19th century. Special chapters are devoted to the anatomy, physiology, etiology, pathology, symptomatology, diagnosis, complications and prognosis. They are discussed in great detail and in a clear, convincing style. The paragraph on diet as a causation is most interesting. That diet plays a large part in the disease is well-known and accounts for the lower incidence among Indians.

Roller millet flour is supposed to be a cause of the increased frequency of appendicitis amongst the highly civilized nations. On the other hand, other authors attribute it to an excess of meat and fat in the diet.

A special chapter is devoted to appendicitis in children and the author emphatically states that the only treatment for this ailment in children is surgical—no matter in which stage the patient is seen. The chapter on treatment is excellent. Early diagnosis, early operation by a competent surgeon, avoidance of purgatives and morphia are the essentials that diminish the death rate in appendicitis.

The author quotes Rutherford Morrison who says: "There would be no percentage of deaths from appendicitis if every case commencing with acute pain, developing tenderness and rigidity of the abdomen and quickening of the pulse were operated upon within 12 hours."

The author advises the McBurney or grid-iron incision in acute cases, but advocates the Battle incision for all chronic cases in which it is necessary to explore or operate upon the upper abdomen or pelvis. In England the tendency is nowadays to give up the Battle incision and replace it by the paramedian incision for less obvious cases where inspection of the abdominal contents may be required.

The monograph is well brought out; the illustrations are good; it is a book which will be read with great interest by the general practitioner as well as the surgeon and we strongly recommend it as a useful addition to any medical library.

E. O. G. K.

Annual Reports.

REPORT ON THE WORKING OF THE PUNJAB MENTAL HOSPITAL, LAHORE, FOR THE YEAR 1927. GOVERNMENT PRINTING PRESS, PUNJAB. PRICE RE. 1-1.

SEVERAL features of interest are recorded in the Punjab Mental Hospital Report for 1927.

Admissions, Discharges, Etc.—1. *Population.*—The number of patients remaining under treatment on the 1st January, 1927, was males 665 and females 182, making a total of 847. During the year 397 patients, of whom 317 were males and 80 females (the figures include re-admissions, and cases sent for observation; some of the latter were discharged without certification) were admitted to the hospital. The total number of patients treated thus amounted to 1,244, being 94 in excess of those treated in 1926.

The average population for the year was 889.88, as compared with 854.19 in the preceding year. The population rose very rapidly during the latter half of the year and on 25th November, 1927, there were no less than 956 patients under treatment. The maximum number of patients under treatment in 1926 was 884.

The total number discharged was 218, as compared with 224 in 1926, of whom 132 were discharged as cured, 58 as improved, 6 not improved and 22 otherwise.

The percentage of cures to the daily average strength was 14.48 as compared with 11.47 in 1926.

2. *Sickness and mortality.*—The death rate expressed as a percentage of the average strength was 11.45 as compared with 9.25 in 1926 and 14.23 in 1925. Out of 102 deaths, influenza and pneumonia each accounted

for 19. During the year 55 patients were treated for pneumonia with 19 deaths and 81 for tuberculosis of various forms with 15 deaths. Bowel diseases such as dysentery, diarrhoea, colitis and enteritis accounted for 86 admissions to the hospital with 9 deaths. There were 11 deaths from epilepsy and status epilepticus.

3. *Criminal Patients.*—There was an increase of 20 in the number of patients treated during the year under review. No less than 53 criminals were admitted, making a total of 207 patients under treatment. There were 164 criminals in the institution at the close of the year.

4. *Accommodation, New Buildings, Etc.*—The new hospital section on the female side has not yet been completely taken over, as the lead of water was insufficient for the water carriage system, which has been installed. A new tube well has been sunk in order to remedy this defect.

The report of Major Lodge-Patch, Superintendent of the Hospital and Mr. Ram Chandra, i.c.s., who were deputed by the Punjab Government (Ministry of Local Self-Government) to visit mental hospitals in other provinces was received during the year and is under the consideration of Government.

The so-called "Hospital Section" is not suited for the treatment of patients; and the Superintendent has made proposals for remodelling the buildings so as to make them suitable for modern methods of treatment of mental patients.

Reference has been made in the previous paragraph to the water carriage system which has been installed in the Female Mental Hospital and is working satisfactorily; the nuisance of insanitary open drains has been abolished, and it is hoped that a similar system of sanitation will be introduced on the male side in due course.

The sanitary condition of the Mental Hospital will continue to be unsatisfactory until the Mian Mir Storm Water Channel is prevented from being a breeding ground of mosquitoes. The Director of Public Health has been asked to recommend measures for dealing with this menace to the health of the patients in the hospital and other inhabitants of the neighbourhood.

During 1927, there were no deaths by violence; and no fatal accidents. There were 3 escapes during the year under report but all the patients were recovered.

As in previous years, the manic-depressive psychoses account for the greatest number of admissions—no less than 199 out of a total of 397. Seventy-one cases of insanity due to cannabis indica during the year were admitted and 29 cases of dementia præcox.

The Superintendent, Major C. J. Lodge-Patch, M.C., I.M.S., is making every effort to bring the hospital into line with the high standards now prevailing in similar institutions in Western countries.

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA, FOR 1926, VOL. I, WITH APPENDICES. CALCUTTA: GOVERNMENT OF INDIA. CENTRAL PUBLICATION BRANCH. 1928. PRICE RS. 2-4, OR 4s. NET.

INTRODUCTION.

THE Annual Report of the Public Health Commissioner with the Government of India for 1926 has just come to hand. The very brief synopsis given below is extracted from Vol. I of the report which deals with the "Civil" Health: Vol. II is devoted to the Health of the Army in India.—(EDITOR, I. M. G.)

On the State of the Public Health in British India.

The defects in the system of registration and compilation of vital statistics in India have been commented on *ad nauseam* in previous reports; but it has also been shown that, provided their limitations are intelligently borne in mind, these vital statistics provide a fairly reliable groundwork of fact on which public health policy may be founded. It need hardly be reiterated that a report such as this, condensing as it

does the available information of the health of a sub-continent, is not an exhaustive guide to the student, who should refer to the detailed reports of provinces and municipalities.

The chief statistical facts, relating to the public health in British India in 1926, are now set out:—

(1) the birth rate rose from 33.65 per mille in 1925 to 34.77 per mille in 1926;

(2) the death rate rose from 24.72 in 1925 to 26.76 in 1926;

(3) the infantile death rate rose from 174 in 1925 to 189 in 1926.

POPULATION.

The population of British India within the registered areas has been stated in decennial periods and age-groups in the following two tables which are compiled from the provincial public health reports.

A.—Population under registration.

Year.	Population for British India (under registration).
1872	180,508,677
1881	184,998,433
1891	206,608,713
1901	224,280,118
1911	238,688,119
1921	241,419,723
1922	241,419,723
1923	241,469,026
1924	241,419,726
1925	241,469,026
1926	241,471,383

B.—Population under registration by sex and age. (The figures against age-groups exclude Delhi and Ajmer-Merwara for which figures are not available.)

Age-groups.	Males	Females.	Persons.
All ages ..	123,944,788	117,526,455	241,471,384
0-5 years ..	14,449,405	15,376,816	30,226,211
5-10 " ..	13,248,639	17,477,030	35,725,669
10-15 " ..	15,355,643	12,529,322	28,484,965
15-20 " ..	10,512,220	9,718,892	20,231,112
20-30 " ..	20,413,515	20,444,963	41,358,528
30-40 " ..	18,029,771	16,377,084	34,426,855
40-50 " ..	12,539,172	11,316,364	23,855,536
50-60 " ..	7,619,020	7,118,253	14,737,273
60 and upwards	0,283,478	6,569,357	12,846,835

Estimated population for the year 1926 is available for Central Provinces, Madras and the Punjab, the figures being 14,509,867 (an increase of 597,107 over the census figures), 45,102,311 (43,307,590 according to previous intercensal increases) and 21,538,849 (an increase of 1,021,243 over the census figures), respectively.

RAINFALL AND OTHER WEATHER CONDITIONS.

Through the courtesy of the Director-General of Observatories, the details of the chief features of the rainfall and other weather conditions during 1926 are appended.

Taking the year as a whole rainfall averaged six per cent. above normal. The greatest defect—25 per cent.—occurred in Hyderabad South; excesses of 21 per cent. or more were recorded in the Bay Islands, Upper Burma, the North-West Frontier Province, Sind, Rajputana, Gujarat, Central India East and the Central Provinces West; in the remaining sub-divisions, rainfall was within 17 per cent. of the normal.

BIRTHS.

British India.—Births numbered 8,395,679 or 270,271 more than the figure for 1925, the birth rate being 34.77 against 33.65, in 1925 and 33.35, the mean of the previous five years. The increase was shared by all the provinces, except Delhi, Bengal, and Ajmer-Merwara, where the decrease was 0.61, 2.2 and 1.81, respectively. With the exception of Bengal, Coorg, Burma and Ajmer-Merwara, all provinces showed an increased birth-rate as compared with the quinquennial mean.

DEATHS.

British India.—Deaths numbered 6,460,610 as compared with 5,967,918, in the preceding year—an increase of 492,692. Registered births exceeded deaths by 1,935,069 against 2,157,490 in 1925; all the provinces with the exception of Delhi, Coorg and Ajmer-Merwara having contributed to this in the following order:—Madras (431,764), United Provinces (413,170), Bihar and Orissa (393,563), Bombay (162,871), Central Provinces (162,748), Bengal (125,183), Punjab (105,158), Burma (72,095), Assam (53,446) and North-West Frontier Provinces (18,036).

The death rate was 26.76 as against 24.72 in 1925 and a quinquennial mean of 26.53. The urban death rate was 32.49 against 29.65 and the rural rate was 26.21 against 24.30 in 1925. In Delhi and Assam, the rural rates exceeded the urban ones; in Coorg the urban rate exceeded the rural one by 45.78, in Burma by 18.63 and in United Provinces by 16.81.

STILL-BIRTHS.

These continue to be recorded over a very limited area in British India.

Bombay Presidency.—11,550 still-births or 1.63 for every 100 live-births, were registered as against 10,852 or 1.63 in 1925; while the following percentages of still-births to live-births show the range of variation:—Bombay City 8.07, Kanara district 5.16, Dharwar 3.21, Bijapur 3.01, Kolaba 2.77, Surat 2.76, Belgaum 2.37, Karachi 2.12, Bombay Suburban 2.04 and Ahmednagar 0.23 per cent. of live-births.

United Provinces.—13,948 still-births were recorded against 14,404 in 1925 and 15,610 in 1924, a steady decline; Gorakhpur district as usual heading the list with 3,249, ascribed to defective reporting. In many cases still-births are attributed to venereal disease; the question of creating an agency to deal with venereal disease was under the consideration of Government.

Burma.—There were 2,836 still-births in urban and rural areas (9.59 per mille of registered births). Amongst towns, Henzada (110.52), Pegu (100.47), Pakokku (97.60), Bassein (89.82), Moulmein (72.88) and Rangoon (67.00) returned high rates, whilst the rural areas recording high rates were Kyaukse (19.33), Sandoway (12.83), Mandalay (10.06), Amherst (9.93), Magwe (9.08) and Minbu (8.25).

Central Provinces.—13,786 still-births were recorded (13.146 in 1925). The Chhatisgarh and Berar districts returned the largest numbers. In some districts venereal disease was said to be responsible for most of the still-births.

Madras Presidency.—Still-births numbered 21,032 (11.447 males and 9,585 females).

In many rural areas and municipal towns instances of faulty registration were recorded, i.e., still-births were either not registered at all or were being included among both births and deaths.

Bengal Presidency.—59,571 still-births were reported (62.281 in 1925), showing an increase of 3.0 per cent. over 1925 in proportion to total births.

INFANT MORTALITY.

1,587,091 deaths or 24.6 per cent. of total mortality occurred during the first year of life against 1,416,983 and 23.7 per cent., respectively, in 1925. In England and Wales the corresponding figures for 1925 and 1926 were 11.3 per cent. and 10.7 per cent., respectively.

The infantile death rate calculated on the births recorded during the year was 189 as against 174 in

1925 and 189 in 1924. Every province recorded an increase, except Coorg. In British India 749,086 (47.2 per cent.) of the infantile deaths occurred during the first month of life, against 702,571 (49.58 per cent.) in 1925. This equals 89 per 1,000 of live-births—a rate, again, in excess of the total infantile mortality rate in England and Wales, which was 70 per 1,000 births registered.

MATERNAL MORTALITY.

Bombay Presidency.—The number of women who died in child-birth increased from 3,502 in 1925 to 4,392 during 1926; while Bombay city registered 143 deaths (114 in 1925): in other words, in 1926 in the Presidency as a whole, one woman died in child-birth for every 162 live-births (1 in 190 in 1925). The urban and rural figures were one per 85 and 193, respectively, against 111 and 218 in the preceding year. Amongst the collectorates, the mortality from this cause was again greatest in Kanara where, for every 47 births, one mother is said to have died (1 in 46 in 1925). The towns in Sind continued to return inordinate rates, Larkana one maternal death in every 30 births, Shikarpur 1 in every 31 and Sukkur 1 in every 52.

Madras Presidency.—7,142 deaths from causes associated with child-birth were registered.

The Director of Public Health attributes this steady increase to better registration, but again points out that the extent of mortality from this cause is still very much underestimated.

Central Provinces and Berar.—3,391 deaths were recorded—579 in municipal towns and 2,812 in rural circles, as compared with 2,520 deaths in 1925—426 in municipal towns and 2,094 in rural circles. Most of these deaths are said to be due to interference by the untrained dais and also to want of proper care and treatment after delivery.

Bengal Presidency.—The registration of maternal deaths is said to be gradually improving. During the year, 3,228 deaths were recorded against 2,790 in 1925.

United Provinces.—1,817 deaths were reported—1,408 in 1925.

Burma.—401 deaths from child-birth were recorded in towns (339 in 1925)—or 11.18 per 1,000 registered births. The highest rates were returned in Pakokku (47.95), Akyab (26.41) and Tavoy (23.33).

Maternity and Child-Welfare Work.—A more detailed account of the various provincial activities on lines similar to those of last year follows. It depicts roughly the position arrived at in the various provinces.

Bengal Presidency.—The educational propaganda and publicity branch was increasing in popularity and utility. 312 lectures were delivered with magic lanterns and 50 bioscopic shows with departmental films were given. District boards, municipalities and other local institutions sought help of this branch. 50 sets of multi-coloured magic lantern slides on various preventible diseases were prepared and leaflets and pamphlets published and distributed. A new film on maternity and child-welfare was produced and was well received by the public.

During the year grants-in-aid for dai-training were made to the various local bodies for starting 100 training classes (of 10 dais each). A total of 1,094 dais received training in 101 classes, started by 32 local bodies and 3 health societies.

United Provinces.—The schemes for the improvement of indigenous dais and that for the training of probationers are reported to have made satisfactory progress. Baby week celebrations held under the United Provinces Branch of the All-India Maternity and Child-Welfare League during 1926, were carried out with success in 32 districts in the province. The Council of the League held one meeting during the year. The local Government increased their grant from Rs. 26,000 to Rs. 50,000 during the year. Of this, the provincial branch distributed Rs. 36,000 as donations to the branches already in existence and as a preliminary gift to other districts only to encourage them. At present maternity and child-welfare work is being carried out in 22 districts; 12 more are expected to

start work in the near future. The Indian Red Cross Society (United Provinces) gave Rs. 500 for central expenses in connection with the baby weeks; the Council of the All-India Lady Chelmsford League, Delhi, also gave their usual grant of Rs. 3,000.

Burma.—The Burma branch of the Indian Red Cross Society made grants, aggregating to Rs. 2,904, to various infant welfare societies from the Child-Welfare Endowment Fund. The number of societies now affiliated is twelve.

Madras Presidency.—In municipal areas 406 (343 in 1925), trained midwives attended 36,564 births; in rural areas 542 (497 in 1925), midwives attended 45,300 births. The number of maternity relief and child-welfare centres, which had increased from 23 in 1923 to 58 in 1925, decreased to 53 in 1926; this is deplorable.

Central Provinces.—A special welfare committee of the Red Cross Society was constituted for organising and expanding maternity and infant welfare work. The local Government made a grant of Rs. 20,000 for the purpose. Up to the end of December, 1926, 13 centres were sanctioned. Great difficulty was experienced in securing trained health workers and dais. Centres were also opened at Wardha and Burhanpur and more will be opened at Seoni and Khamgaon. The Red Cross gave Rs. 1,800 for a centre in Jubbulpore during 1927. Nagpur possesses 5 centres, 3 managed by the municipality, one by the Red Cross Society, and one by the provincial welfare committee in connection with the health school.

Regular informal clinics were held for mothers where they were taught mothercraft, sewing and principles of hygiene and feeding. In two of the infant welfare centres managed by the municipality, dais were trained.

Bombay Presidency.—The ten sanitary associations continued their useful work. That at Karachi conducted 1,059 maternity cases (894 in 1925) and organised a "baby and health week." There were 7 midwives in charge of different quarters. The lady health visitors paid 3,485 house-to-house visits. In the Bherumal Thakurdas maternity home, a gynaecological department was introduced; 361 labour cases were conducted and 850 cases of gynaecological operations were performed; out of the 24 cases of premature birth conducted 18 died. The training of native dais in maternity was ably carried out at Hyderabad, and was extended to seven centres; 55 dais were under instruction, and 192 were under supervision; 326 midwifery cases were superintended. The association at Shikarpur delivered ten public lectures and distributed leaflets and pamphlets. That at Broach delivered 32 lectures in the city and 25 in the district with magic lanterns; a health show was also held; 10,000 quinine tablets were distributed free and 20,000 sold in rural areas and the city; leaflets on consumption, child-welfare, malaria and fly nuisance were also distributed free. The pure milk supply branch of this association distributed at cost price 3,408 maunds and 2 seers of milk to the public at three centres. The Ahmedabad association organised 52 magic lantern lectures. Other associations also worked according to local requirements and opportunities. The "health and baby week" movement was celebrated in many important towns. The Assistant Director of Public Health, though unable to attend personally at these health shows, co-operated with the local organisers in their inauguration and management.

Punjab.—The Punjab health school which trains lady health visitors for the province was continued during the year as a private concern, conducted and financed by the Lady Chelmsford League (Punjab Branch). The Government has, however, agreed to provincialise this school which has accordingly been taken over by the public health department with effect from 1st April, 1927. 8 students were admitted to the school, and all of them passed. 16 local bodies were by the end of the year employing lady health visitors and most of them had opened maternity and child-welfare centres; those at Simla and Gurgaon are quoted as instances of excellent work. The question of subsidising this movement was under discussion with Government.

Assam.—A child-welfare centre, instruction is given to mothers, has been opened in Shillong. In other towns "baby week" was held. Magic lantern demonstrations and lectures on child-welfare are given regularly by medical officers during the course of their visits to villages.

Bihar and Orissa.—Maternity and child-welfare work is in its infancy in this province, but the problem is being tackled. As a result of the movement inaugurated in India by Lady Reading, a Council has been formed and funds raised. In Patna, a start has been made by opening two centres under a maternity supervisor; in Cuttack a centre has been opened and here definite results are evident. It is estimated that one half of the births in this town were supervised by the workers; another centre has been opened at Balasore and another was under contemplation at Darbhanga. Up to the end of 1926, 488 dais were trained in methods of cleanliness during labour.

MALARIA.

Punjab.—The annual forecast issued by the public health department predicted with remarkable accuracy the distribution and intensity of malaria epidemic in the province. The unhealthiest month in respect of fever mortality, as is usual in years when malaria assumes epidemic form, was the month of October when 58,076 fever deaths were registered (43,659 in 1925). The districts showing the highest death rate were those affected by the malaria epidemic.

United Provinces.—749,868 malaria deaths were recorded. Bulandshahr, Meerut, Saharanpur, Moradabad and Bijnor districts showed the highest fever mortality, and Fatehpur, Ballia, Jaunpur, Allahabad and Ghazipur the lowest.

Bihar and Orissa.—Heavy floods in September in Orissa resulted in an increase of malaria cases. A spleen census of children was being taken. The figures so far obtained give a high percentage of enlarged spleens and indicate a very high incidence of malaria in most districts.

Bengal.—Fever death rate was highest in November and lowest in July. 458,208 deaths from malaria (ratio 9.8 per mille) were reported. Malaria was responsible for 55.7 per cent. of the fever mortality and 39.8 per cent. of the total mortality. For an analysis of the incidence of fevers and malaria by divisions and districts, and towns and rural areas, the provincial report should be consulted.

Assam.—A decreased fever death rate was again recorded—chiefly attributable to an actual decrease in the prevalence of kala-azar. The fever death rate was the highest in Goalpara district and the lowest in Sibsagar.

Madras Presidency.—The fever death rate per mille of population was 8.3 against 7.7 in 1925. The Director of Public Health thinks that a very large proportion of fever deaths is certainly due to malaria and urges for anti-malarial work and the permanent employment of a large anti-malarial staff.

Bombay Presidency.—The death rate from malaria for the Presidency as a whole was 2.83, while exclusive of Sind the rate was 1.18 only. Sukkur in Sind was the district of greatest severity with a rural death rate (malaria) of 15.13, followed by Thar and Parker with a rate of 14.50, Nawabshah 12.62, Hyderabad 11.34, Larkana 11.04, Upper Sind Frontier 10.81 and Karachi 9.18—due to excessive flooding and heavy rainfall.

Central Provinces.—All the districts participated in the increase in fever mortality (252,609 deaths against 204,667 in 1925). October and February were the months of the highest and lowest mortality, respectively. A scheme for a malaria bureau or field unit (for malarial surveys) was submitted to Government.

RELAPSING FEVER.

Punjab.—The disease was detected in 6 districts but it did not assume epidemic proportions. 304 cases and 143 deaths were recorded against 922 cases and 196 deaths in 1925. The case mortality was 47 per

cent. (21 in 1925). The districts affected were Attock, Multan, Muzaffargarh and Dera Ghazi Khan.

United Provinces.—716 deaths were recorded though the district medical officers of health reported no epidemics of the disease in any of the districts.

Madras Presidency.—Mild outbreaks were reported from Coimbatore, Trichinopoly, Madura, the Nilgiris, Nellore, and Kurnool districts. The Kurnool district registered 295 cases and 56 deaths, Trichinopoly 84 cases and 34 deaths, Madura 29 and 7 and Nellore 27 and 7.

Central Provinces.—No outbreak of the disease occurred anywhere. Two mission hospitals in Mandla district treated ten cases though no confirmatory evidence was available. Khandwa and Jubbulpore treated one case each.

Bengal Presidency.—Relapsing fever was responsible for 0.04 per cent. of fever mortality and caused 3,075 deaths (0.07 per mille) as compared with 3,161 deaths (0.07 per mille) in 1925 and 6,798 deaths (0.14 per mille) in 1921. Calcutta has reported no cases of relapsing fever during the last three years.

KALA-AZAR.

United Provinces.—151 deaths (95 in 1925) were recorded. The local Government contributed Rs. 3,000 in connection with the Commission appointed by the Government of India in 1924 to inquire into the origin and progress of kala-azar and the measures necessary to combat it.

Assam.—4,176 deaths (6,365 in 1925, 5,585 in 1924, 4,131 in 1923 and 2,292 in 1922) occurred. 49,385 cases were treated (60,940 in 1925). The fall in deaths and cases both indicate that the disease is now under control and its further spread has been arrested. The percentage of deaths to the total treated was 8.48 (10.44 in 1925). The treatment is said to be growing in popularity and the number of cases stopping treatment before completion fell by 1,212. Special kala-azar hospitals have been opened in heavily infected areas. Hospitals and dispensaries with their out-centres treating kala-azar in the province numbered 415. The surveys which have been strenuously carried out in the villages have revealed the fact that fewer cases are being discovered in the earlier stages of the disease. Research work was being carried out in the kala-azar research wards of the Pasteur Institute and Medical Research Institute at Shillong with certain organic aromatic compounds of antimony. The question of using urea stibamine for all kala-azar cases was under consideration.

Bombay Presidency.—Two deaths were recorded in Bombay City.

Central Provinces.—Cases were reported from Raipur (3 cases) and Bhandara (1 case).

Bengal Presidency.—14,275 deaths (16,766 in 1925) were recorded, the rate per mille being 0.31 (0.36 in 1925). Kala-azar accounted for 1.7 per cent. of fever and 1.2 per cent. of total mortality. Kala-azar treatment centres have been opened in districts. The Central Co-operative Anti-malarial Society and the Bengal Health Association received grants from provincial revenues for the treatment of kala-azar cases. The former worked in 48 centres but for want of cases 10 had to be closed. A total of 1,327 new kala-azar cases were admitted to these centres. The latter with its 41 kala-azar centres treated 4,731 cases.

INFLUENZA.

Bombay Presidency.—As compared with the previous year, the mortality from influenza rose slightly (i.e., 362 against 192 in 1925).

Central Provinces.—The disease prevailed in a mild form, the number of cases treated being Bhandara 325; Jubbulpore 2,214; Saugor 625, with 10 deaths; Damoh 596; Seoni 826; Mandla 430, with 3 deaths; Hoshangabad 140; Raipur 613; Amraoti 4,151 and Yeosmal 1,116. Mild cases occurred in Buldana also.

Bengal Presidency.—Influenza accounted for 1,817 deaths—0.03 per mille against 1,901 deaths in 1925—0.04 per mille.

Punjab.—433 cases and 52 deaths were recorded. The deaths were distributed as follows:—Kangra 26, Muzaffargarh 21 and Sialkot 5.

In Amritsar and Dera Ghazi Khan districts also the disease prevailed to some extent.

United Provinces.—Sporadic cases occurred in some districts.

Burma.—79 deaths were recorded in towns.

ENTERIC FEVER.

Bombay Presidency.—The accuracy of death figures especially in rural areas is not to be relied upon. 124 deaths were recorded in Bombay City (139 in 1925), 1,265 in Southern Registration district. 511 in Central, 342 in Sind, 31 in Guzerat and 3 in Western Registration districts.

Punjab.—6 cases with no death were registered in Simla town (49 cases with 7 deaths in 1925).

Central Provinces.—111 cases of enteric fever were treated in Jubbulpore, 38 in Raipur and 16 in Bhandara. The civil surgeon, Jubbulpore, remarks that the diagnosis of out-patients was doubtful.

United Provinces.—10,266 deaths were recorded.

Bengal Presidency.—The enteric deaths fell from 7,752 in 1925 to 5,368 in 1926, the death rate being 0.11 per mille (0.17 in 1925). 71 towns out of 116 did not report a single death from this cause.

Burma.—348 deaths occurred in towns. Pyapon returned the highest ratio. The disease continued in Mandalay throughout the year.

BERI-BERI.

Bengal Presidency.—Cases of epidemic dropsy were noticed in the towns of Hooghly and Chinsura and in some villages in Burdwan, Howrah, Faridpur and 24 Parganas districts. In Khulna district an outbreak of the disease was reported both in towns and rural areas. In Bakarganj district 251 cases with 13 deaths of epidemic dropsy were detected.

Central Provinces.—Raipur recorded one case of beri-beri.

Madras Presidency.—In Ganjam district epidemic dropsy appears to break out in an epidemic form at the same time (April and May) each year and subsides with the advent of the rains. 102 cases were discovered and in 88 of these, the infection was traced to two endemic foci in the union village. The death rate was 6 per cent. The disease is said to be gradually assuming larger proportions and a further investigation is called for.

RESPIRATORY DISEASES.

Central Provinces.—The deaths from this cause numbered 40,251 (2.89 per mille) as against 31,710 (2.28 per mille) in 1925.

Jubbulpore continued to return the highest mortality, viz., 11.71 per mille (9.33 in 1925). It is again attributable to cold and rain.

Assam.—There were 5,300 deaths, a rate of 0.77 per mille.

Burma.—There were 11,638 deaths (1.08 per mille). Towns returned 9,126 deaths.

Bombay Presidency.—There were 103,038 deaths (83,047 in 1925), with a rate of 5.38 per mille (4.33 per mille in 1925), the highest rate recorded since the influenza year 1918, when it was 6.11 per mille. Guzerat Registration district recorded the highest number of deaths (30,419). Among Collectorates Surat, Kaira, Broach, Ahmedabad, Poona, Ahmednagar, Nasik and Khandesh each returned the highest rates ranging between 12.24 and 5.09 per mille.

North-West Frontier Province.—1,452 deaths were registered (1,549 in 1925).

Punjab.—There were 57,426 deaths—a rate of 2.80 per mille (2.65 in 1925). The urban and rural rates were 6.72 and 2.35, respectively.

United Provinces.—30,260 deaths (0.67 per mille) were registered, the rate being 0.09 and 0.07 in excess of 1925 and the quinquennial mean, respectively. Hamirpur and Lucknow with death rates of 7.70 and

4.24 per mille returned the highest mortality. The urban mortality was 7.22 and the rural one 0.21.

Madras Presidency.—The number of deaths registered was 85,602 (2.1 per mille) as compared with 74,591 (1.8 per mille) in 1925.

Bengal Presidency.—These diseases accounted for 30,589 deaths (0.66 per mille) as compared with 27,325 (0.59 per mille) in 1925. While pneumonia and phthisis deaths were on the increase, influenza was slightly less than previously.

PNEUMONIA.

United Provinces.—The deaths numbered 5,914 (0.13 per mille) as against 4,993 (0.11 per mille) in 1925.

Bombay Presidency.—20,654 deaths were reported (1.08 per mille) against 18,950 (0.99 per mille) in 1925. Sind Registration district recorded 4,280 deaths, Guzerat Registration district 4,098, Western Registration district 1,854, Central Registration district 1,655, and Southern Registration district 228. Bombay City recorded 8,539 deaths (8,450 in 1925). The urban and rural rates were 3.79 and 0.42, respectively (3.55 and 0.37 in 1925). The highest urban and rural rates were those of Hyderabad (9.95) and Surat (2.60), respectively.

Burma.—The urban areas returned 3,421 deaths (2.74 in 1925). The highest rates were those of Monywa (6.94), Minbu (6.66) and Shwedaung (5.49).

Bengal Presidency.—There were 12,294 deaths (11.259 in 1925), the rates being 0.26 and 0.24 per mille, respectively. Pneumonia was responsible for 1.07 per cent. of total deaths and 4.2 per cent. of deaths due to respiratory diseases.

STATISTICS OF PULMONARY TUBERCULOSIS.

An exact estimate of the present incidence of this disease is still largely one of surmise; but the following notes from the various provincial reports give some idea of its prevalence.

Central Provinces.—1,754 tuberculosis patients (1,703 in 1925) were treated in hospitals and dispensaries. Of these, 463 were treated in Akola district. The disease is said to be far more prevalent than these figures indicate. The Pendra Mission sanatorium (a private institution) had 84 admissions during the year. 7 died and 71 were discharged. Government sanctioned Rs. 1,000 for the purchase of milch cattle for this sanatorium.

Burma.—Tuberculosis of the lungs appears to be increasing in towns; the death rate per mille was 1.66 against 1.65 in 1925, 1.51 in 1924, 1.32 in 1923 and 1.40 in 1922. In certain towns, notably Rangoon, Tharrawaddy, Mawlamyainggyun and Myaungmya the death ratios show a much more marked increase. The proposal to provide a sanatorium at Meiktila was still under consideration.

Bombay Presidency.—21,892 deaths were registered as due to phthisis—i.e., a death rate of 1.14 as against 17,832 and 0.93, respectively, in 1925. The Central Registration district reported the largest number of deaths (5,950), followed by Western (5,460), Guzerat (5,168), Southern (2,655) and Sind (1,120). Bombay City recorded 1,539 deaths (1.34 per mille). The urban and rural figures were 1.83 and 0.97 against 1.58 and 0.77, respectively, in 1925. Highest urban rates were recorded in Dharangaon (6.21), Rander (5.97), Bhiwandi (4.43), Ahmedabad (4.18), Poona (3.71), Nasik (3.16), Pandharpur (3.13), Ilkal (3.12), Hyderabad (3.08), Chipun (3.00), Surat (2.99), and Ratnagiri (2.73); the highest rural rates were those in Kolaba (3.04), Ratnagiri (2.52), Kaira (2.10), and Thana (1.46). The mortality was highest between 20 and 40 years of age. In Guzerat, the congestion in some big cities and certain customs prevailing in some communities like the purdah among the Bohra women, early marriage followed by repeated pregnancies among the better class Hindus, and the practice of conducting confinements in dark and ill-ventilated rooms, were largely responsible for the high death rate from phthisis.

United Provinces.—Phthisis caused 6,380 deaths with a ratio of 0.14 per mille (5,442 deaths with a ratio of 0.12 in 1925). The Lucknow Anti-Tuberculosis League have resolved to establish a special tuberculosis hospital in Lucknow at an estimated cost of Rs. 2 lakhs. The Local Government have promised an annual recurring grant of Rs. 32,000 for its upkeep. A site, free of cost, has been given by the Lucknow University for the purpose. The hospital, when ready, will supply a long-felt want.

Bengal Presidency.—Phthisis caused 7,032 deaths (0.15 per mille) against 6,079 (0.13 per mille) in 1925. 22 towns did not report any deaths from this cause, 13 towns returned death rates of 1.0 per mille and above and the rest below that. A little more than 50 per cent. of phthisis deaths in all towns occurred in Calcutta only. High rates were registered in Kurseong (5.4 per mille) and Calcutta (2.4 per mille). It was responsible for 0.6 per cent. of the total mortality (all causes) and 22.9 per cent. of that due to respiratory diseases.

DYSENTERY AND DIARRHŒA.

256,293 deaths (1.06 per mille) were recorded against 208,412 deaths (0.86 per mille) in the previous year.

CHOLERA.

Statistics in British India.

Bengal Presidency.—There were 59,106 deaths (1.3 per mille) as against 34,276 (0.7 per mille) in 1925, an increase of 85.7 per cent. over the figure for the previous year. Cholera was reported from 590 out of 632 registration circles. 299,079 cholera inoculations were performed, 17,284 wells and 9,588 tanks were disinfected. 100 sanitary inspectors and 25 sub-assistant surgeons in addition to medical officers attached to the public health department co-operated with the local bodies in combating the epidemic.

Bombay Presidency.—The Presidency with only 73 deaths (57 in 1925), remained practically free for another year. The Western Registration district alone returned 43 deaths. Out of a grant of Rs. 15,000 sanctioned by Government for anti-cholera measures Rs. 750 were spent.

Bihar and Orissa.—The death rate rose from 0.5 per mille in 1925 to 0.8 in 1926. Patna district recorded the highest rate (1.8 per mille). Lalganj (12.1), Hajipur (5.9) and Jamalpur (5.1) recorded the highest rates among urban areas. The epidemic cadre of ten assistant surgeons was maintained, as also the reserve of 100 vaccinators for special cholera and other epidemic duties. 5,790 doses of cholera vaccine were issued to civil surgeons from Namkum. A reserve stock of kaolin, bleaching powder and potassium permanganate was supplied to civil surgeons.

Punjab.—Only 87 deaths were recorded (3,049 in 1925). An outbreak of a disease resembling cholera and of indigenous origin was reported from a village just outside Simla. On investigation the disease was found to be clinically indistinguishable from true cholera. The post-mortem and bacteriological findings, however, definitely negated the diagnosis of cholera. No information is available as to the real cause of the disease or the extent to which it was responsible for the total cholera mortality.

United Provinces.—Deaths numbered 6,166 (0.13 per mille) as compared with 7,653 (0.17 per mille) in the previous year. The urban and rural figures were 0.09 and 0.14, respectively. In the 20 districts under the cholera scheme 5,091 deaths from cholera were recorded while the remaining 28 districts returned 1,075 deaths.

Central Provinces.—4,565 deaths were recorded (124 in 1925). Bilaspur district returned the highest mortality (1,482 deaths) and infection was imported by pilgrims returning from Allahabad. 20,778 anti-cholera inoculations were carried out.

Madras Presidency.—Cholera deaths numbered 24,407 (0.6 per mille) against 44,815 in 1925 (1.1 per mille). Tanjore, Tinnevely, South Arcot, Trichinopoly, Coimbatore and Salem districts returned more than 80 per cent. of the total cholera mortality. The rules

governing cholera preventive measures in municipalities were revised and rewritten. As in 1925, cholera was almost wholly confined to the southern parts of the Presidency.

Burma.—6,182 deaths were recorded. Rural areas in Pegu and Irrawaddy divisions and Akyab district together totalled 3,303 deaths as against 1,501 in the rest. The death rate for the province was 0.57 (0.18 in 1925). Owing to the severity of the epidemic, anti-cholera inoculation became highly popular, so much so that 44,314 inoculations were performed (13,965 in 1925) or almost three times the previous figure; 1,000 doses of Besredka's anti-cholera bili-vaccin tablets were purchased and distributed.

Assam.—10,275 deaths (1.49 per mille) were registered against 6,233 (0.90 per mille) in 1925. Kamrup district was the worst affected with a death rate of 6.65 per mille and the source of infection was traced to a mela held at the foot of the Bhutia hills. Cholera inoculation was resorted to with satisfactory results.

PLAGUE.

Statistics in British India.

The mortality (196,249 deaths or 0.81 per mille) was nearly double that of 1925, viz., 117,717 or 0.49 per mille). The Punjab and United Provinces with rates of 5.28 and 1.26, respectively, per mille exceeded the general death ratio.

Bihar and Orissa.—The death rate 0.2 per mille (8,381 deaths) was the same as in the previous year. 20,000 anti-plague inoculations were carried out in Muzaffarpur district.

United Provinces.—57,297 deaths (1.26 per mille) were recorded as against 49,091 deaths (1.08 per mille) in 1925 and a quinquennial average of 1.00. The urban and the rural rates were 2.14 and 1.20 (0.91 and 1.09, respectively, in 1925). Gangoh (18.32), Lakhmipur (17.42), Chandpur (16.59) and Chandausi (15.22) among towns were worst affected. A great diminution of plague mortality occurred in the towns of Agra, Muttra, Aligarh, etc., as a result of the intensive anti-rat campaign carried out there.

Punjab.—Plague was epidemic during the year, being responsible for 108,287 deaths (5.28 per mille), as compared with 37,630 (1.83 per mille) in 1925. Ambala division was the worst affected. A special scheme at an estimated cost of 2½ lakhs was launched in this division. Other affected areas were provided with emergency staff. In addition to standard anti-plague measures, the campaign concentrated its efforts on mass inoculation. All presumptive centres of recrudescence including areas known to be endemic foci of plague were listed for preventive de-ratting. It was intended that all the listed villages should be deratted thrice between August and October, but floods and other difficulties were the retarding factors.

North-West Frontier Province.—With the exception of Peshawar district with 1,575 cases and 630 deaths, the province was practically free, the figures for other districts being 7 fatal cases in Hazara and one fatal case (imported) in Dera Ismail Khan. 24,658 inoculations were performed in Peshawar district.

Central Provinces.—6,486 deaths (5.223 in 1925) were recorded, 3,132 (3.385 in 1925) of which were in Berar. Evacuation and inoculation are growing in popularity. 76,404 inoculations (40,069 in 1925) were carried out. A few cases of plague among inoculated persons were reported in Wardha, 34 with 9 deaths in Jabulpore. 2 deaths in Hoshangabad, 20 cases with 9 deaths in Yeotmal and 2 deaths in Buldana districts.

Madras Presidency.—There were 2,143 deaths or 0.1 per mille. More than 75 per cent. of the total mortality was recorded in the three districts of Bellary (697), Coimbatore (483) and Salem (475). Hospet town (ratio 6.1 per mille) was responsible for nearly 70 per cent. of the urban mortality.

Bombay Presidency.—9,866 deaths (12,601 in 1925) were registered, the ratio being 0.51 per mille (0.66 per mille in 1925). Dharwar, Satara and East Khandesh district continued to return the heaviest mortality. Belgaum, Bijapur and Kanara districts reported milder

epidemics. Inoculation was the chief preventive measure and special inoculators were appointed to supplement the medical officers of dispensaries and private practitioners. Routine ratting operations were carried out throughout the year in Belgaum, Nipani, Sholapur, Pandharpur, Panchgani, Malegaon, Dhulia, Karachi, Hyderabad, Larkana, Mirpur Khas, and Tando Adam, and for shorter periods in many other towns. Systematic evacuation was rarely practised except in a few small towns and some villages. 48,900 persons were inoculated (60,831 in 1925). Among persons inoculated, 53 cases, 18 of whom were attacked within 10 days of inoculation, occurred with 22 deaths.

Burma.—1,007 deaths in rural areas (1,142 in 1925) and 1,899 in towns (2,922 in 1925) were registered.

Delhi City.—Out of the 49 cases with 38 deaths recorded, no less than 48 cases were imported ones, or in other words the city was practically free. Rat destruction was vigorously pushed on. 282,249 rats were trapped and destroyed.

Both provincial medical authorities and local bodies have been alive to the need for endeavouring to institute measures against rats where plague was endemic or severe; but in this matter one would again urge thoroughness and continuity of effort without which results are likely to be disappointing.

Punjab.—In Lahore, the total number of rats destroyed was 256,331 by trapping and 79,458 by baiting. 11,551 rat holes were smoked. In Amritsar 298,097 rats were destroyed and 4,218 holes smoked. 37,512 rats were caught and destroyed, 768 rooms were fumigated and 49,866 rats-holes were closed in Rawalpindi. 99,988 rats were destroyed in Sialkot, 38,108 in Multan and 34,671 in Ferozepore.

Delhi Province.—In Delhi City 282,249 rats were destroyed. 26,072 rats were examined for detection of plague infection and 3 of them were found infected. The total cost of the intensive rat destruction scheme amounted to Rs. 35,791 or Rs. 0-2-4 per person per annum.

Bombay Presidency.—In Bombay City 579,806 rats were collected and destroyed. Of these, 283,050 rats were examined and 1,287 were found infected, giving a ratio of 0.45 infected rats per 100 rats examined.

Central Provinces.—In Nagpur town where 88,871 rats were killed, a rat destruction scheme has been pursued since 1918 with no large outbreak of plague. In Jubbulpore town 75,479 rats were destroyed, in Sconi 5,094, in Amraoti 47,357, in Amraoti Camp 10,753, in Malkapur 15,311, in Bhandara 11,158, in Akola 9,350 and in Yeotmal 9,670. Rat killing was also undertaken in many other towns during the year, e.g. Khamgaon 8,500, Burhanpur 11,884 trapped and 8,407 poisoned, Hinganghat 9,371, Wardha, 5,989, Sihora 5,276, Hoshangabad 7,617, Murtizapur 8,747, Katol 5,430, Khandwa 4,103, Basim 6,225, Karanja 4,744, etc.

Burma.—711,063 rats were destroyed (641,283 in 1925). Rangoon Corporation accounted for 669,184 and rural areas 281. In Bassein town 9,784 rats were trapped and destroyed, 0.26 rats were found infected. 2,651 rats were exterminated in Moulmein town, where as a rule 10 per cent. of the rats were always examined microscopically to ascertain plague infection among rats.

SMALL-POX.

Statistics in British India.

The total deaths from this cause were 117,066 against 85,986 in 1925. Bihar and Orissa headed the provincial list with 34,873 deaths, followed by Bengal with 25,584 deaths, the Punjab with 17,595 deaths, United Provinces with 12,020 deaths and Madras with 10,957 deaths.

Madras Presidency.—The death rate was highest in Bellary and West Godavari districts. More than half of the mortality was registered in seven districts, viz., South Arcot, Madura, Tanjore, West Godavari, Trichinopoly, Bellary and North Arcot. 4,889 (44.6 per cent.) of the total small-pox deaths were in age-group "under one year," 3,662 (33.4 per cent.) between 1 and 10 years and 2,406 (22.0) above 10 years—78 per cent. of the deaths therefore occurred among children

under 10 years of age—surely a strong argument for a much more vigorous vaccination policy for the protection of children.

Assam.—The disease prevailed in an epidemic form in the Sibsagar and Kamrup districts, death rates being 3.57 and 1.19 per mille, respectively. Special regulations under the Epidemic Disease Act making vaccination compulsory have been enforced in these localities. Unscrupulous local opposition to vaccination generally and the habit of secreting cases on superstitious grounds continue to maintain the foci of infection in Sibsagar district. In Kamrup the vaccination inspecting staff was inadequate. Small-pox deaths in the province numbered 4,840 with a ratio of 0.70 per mille.

Bihar and Orissa.—The death rate increased from 0.4 in 1925 to 1.0 in 1926—largely on account of a serious epidemic in Orissa. The epidemic was most severe in Puri, Cuttack and Balasore districts. The vaccination state of the people in Orissa is said to be unsatisfactory due to poverty and ignorance. Among urban areas, the disease was severe in Gaya, Puri, Cuttack and Jugsalai which returned death rates per mille of 9.2, 8.5, 5.1 and 3.9, respectively.

United Provinces.—Small-pox claimed 12,020 deaths (9,373 in 1925), the rate per mille being 0.26 (0.21 in 1925). 3,169 deaths occurred among children under 1 year of age and 5,729 between 1—10 years of age, i.e., 74 per cent.

Punjab.—The mortality during the year (17,595 deaths) was the highest since 1920. 5,214 deaths occurred under 1 year of age and 8,060 between 1—10 years, or three-fourths of the total small-pox deaths. High rates were recorded in Montgomery, Lahore, Lyallpur and Multan districts.

Bombay Presidency.—The death rate was 0.20 against 0.29 in 1925 and 0.23, the quinquennial mean. Of the 3,922 deaths from small-pox, 963 were of infants under one year and 1,715 of children between one and ten years.

Bengal Presidency.—There were 25,584 deaths (17,436 in 1925), the ratio per mille being 0.5 (0.4 in 1925). The districts of Pabna, Bogra, Murshidabad, Howrah, Burdwan and Birbhum among themselves accounted for 37.2 per cent. of the total mortality. 8.3 per cent. of the mortality occurred among infants and 20.9 per cent. in children between 1 and 10 years—thus indicating the necessity for local bodies to direct their attention more vigorously to primary vaccination.

ANKYLOSTOMIASIS.

Burma.—27,514 prisoners were examined for ankylostoma infection in 24 jails, against 17,297 in 13 jails in 1925. Of these 9,141 or 33.22 per cent. were found to be infected (5,785 or 33.45 per cent. in 1925). Rangoon jail reported the heaviest percentage of infection (58); Henzada reported 46 per cent.; and Prome 43. In Magwe jail, among 932 prisoners only three cases of infection were found; in Katha jail two cases of light infection among 496 prisoners; while among the 186 prisoners in the Mogok jail there was not a single case.

Madras Presidency.—31,493 examinations were made to ascertain the presence of hookworm infections; of these 26,464 or 84 per cent. were found positive. Malabar district showed the highest intensity of infection, and Cuddapah the lowest. The work in North Arcot district had to be abandoned in favour of Madura district, where the district board agreed to finance an experimental scheme for rural sanitation. General hookworm surveys were made in Tanjore, at Mandapam Camp, in Malabar and South Kanara. Selected areas in Chittoor and Cuddapah districts were also surveyed.

Central Provinces.—Apart from hookworm there is no doubt that helminthic infection, especially roundworm, is very extensive amongst the people of this province. The Director of Public Health estimates the incidence at least 20 per cent. in the case of hookworm and 15 per cent. in the case of roundworm. It is said that the black cotton soil of Berar is inimical to the survival or growth of the hookworm larvae.

LEPROSY.

Madras Presidency.—The district health officers were required to make as accurate an estimate as possible of the leper population in their districts as the census figures of 1921 are thought to be obviously an underestimate. The effort has met with little or no success.

Central Provinces.—454 cases of leprosy were treated in hospitals and dispensaries. 637 patients were treated at leper asylums. Such asylums exist in Patpara (Mandla district), Raipur and Dhamtari (Raipur district), Champa and Mungeli (Bilaspur district), Chandkhuri (Drug district), Kothara (Amraoti district) and Rajnandgaon (Rajnandgaon State). The Deputy Commissioners of Raipur and Bilaspur recommended a leprosy survey being undertaken to ascertain the areas where it is most prevalent. Out of the subscriptions amounting to Rs. 2,07,777-4-0 promised for the British Empire Leprosy Fund (excluding irrecoverable sums), Rs. 2,06,737-2-0 have been collected. It is hoped to start leprosy clinics at selected dispensaries and also to provide special treatment at all dispensaries.

Eight assistant medical officers were given the necessary training in the treatment and diagnosis of leprosy at the special leprosy class held at Champa in Bilaspur district.

Burma.—The provisions of the Indian Lepers Act, 1898, were extended to the whole of Burma; and lepers were prohibited by Government Notification from following certain trades and businesses. Ward headmen, village headmen and the warders of the Rangoon leper asylum, Kemmendine, and St. John's Asylum, Mandalay, were empowered to arrest within their jurisdiction, without warrant, any person who appears to be a pauper leper or any leper who escapes from or leaves the asylum. The local Government have also sanctioned as an experimental measure for two years the establishment of three or more dispensaries for the treatment of lepers in selected leper villages for which Rs. 27,000 were provided in the budget estimates for 1927-28. A leper clinic was opened by Government at the Rangoon General Hospital. Government contributed Rs. 6,000 to the Home for lepers, Mandalay, for a new ward. Proposals for extending the accommodation of the existing asylums and for a leper colony in the province were under the consideration of the local Government.

At the four leper asylums at Kemmendine, Moulmein and Mandalay, 24,425 patients were treated.

Twenty-three lepers from the Indian ports (14 in 1925) disembarked at Rangoon. All except one were allowed to proceed to their destination.

STATISTICS FOR RABIES.

Central Provinces.—Anti-rabic centres increased from two to five. Rabies is said to have caused 159 deaths (187 in 1925). 478 dog-bite cases and 36 cases of bites by other animals were recorded in municipal and other towns, and 228 and 24, respectively, in rural areas. The total number of patients treated at the five centres were Nagpur 513, Hoshangabad 122 with 2 deaths, Akola 157 with 2 deaths, Jubbulpore 341 with 4 deaths, and Raipur 39. 15,681 stray dogs were killed in municipal towns (12,950 in 1925).

Bombay Presidency.—234 deaths were reported (151 males and 83 females), 45 in towns and 189 in rural areas.

Punjab.—172 deaths, of which 34 were in towns and 138 in rural areas, were reported. The provincial bacteriological laboratory of the King Edward Medical College at Lahore treated 2,178 patients (197 Europeans and 1,981 Indians).

Madras Presidency.—488 deaths were registered—100 in towns and 388 in rural areas.

Bengal Presidency.—349 deaths from this cause were recorded during the year—65 in towns and 284 in rural areas. Calcutta recorded 36 deaths. The death rate was highest in Calcutta and Nadia (0.03).

MORTALITY FROM WILD ANIMALS.

The total number of persons killed by wild animals in British India during 1926 amounted to 1,987, as against 1,962 in the previous year and 2,587 in 1924.

Tigers were responsible for 875 deaths, leopards for 183, wolves for 367, bears for 96, elephants for 58 and hyænas for 15. Deaths continued to be highest from tigers in Madras, from leopards in the Central Provinces and Berar, from wolves in the United Provinces, from bears in Bihar and Orissa and from elephants in Assam. Of the 393 deaths from "other animals" about 41 are assigned to wild pigs and 151 to crocodiles and alligators. The highest number of deaths from all wild animals occurred in the United Provinces (532), Madras, Bihar and Orissa and the Central Provinces and Berar coming next in order. The mortality from elephants showed a marked decrease. The mortality in the majority of the provinces was less than in the previous year, but in the United Provinces, Bengal, the Punjab and Burma it was slightly greater.

Deaths from snake-bite increased from 19,258 to 19,718. Increases occurred in Madras, Bombay, Bengal, the United Provinces and Burma, but the Punjab, Bihar and Orissa, the Central Provinces and Berar and Assam have reported decreases.

During the year under review 23,689 wild animals were reported to have been destroyed, of which 1,288 were tigers, 4,247 leopards, 2,633 bears and 3,025 wolves. A sum of Rs. 1,40,061 was paid in rewards, against Rs. 1,55,667 in the previous year. The number of snakes destroyed in India proper increased from 41,004 to 46,012 and the rewards paid for their destruction were Rs. 1,615 as against Rs. 1,579 in the previous year.

VACCINATION AGAINST SMALL-POX.

Vaccination operations increased from 11,987,640 (8,656,193 primary and 3,331,447 revaccinations) in 1925-26 to 12,260,977 (8,631,379 primary and 3,629,598 revaccinations) in 1926-27. Bengal contributed largely to the increase. Delhi, United Provinces, North-West Frontier Province, Madras, Coorg, Bombay, Burma and Ajmer-Merwara all recorded decreases. In Delhi the decrease was attributed partly to the effects of malaria in the autumn; in the United Provinces the appointment of new vaccinators in place of the experienced ones who were deputed to the Kumbh fairs accounted for the decrease; in the North-West Frontier Province and Burma the decrease was ascribed to the epidemic of small-pox not being as severe as in the previous year: in Madras the reduced incidence of small-pox in some districts and prevalence of cholera, lack of unprotected children, etc., in others were the chief causes; in Bombay the prevalence of cholera retarded progress; and in Burma it was ascribed to a reduced incidence of small-pox. Bihar and Orissa, Delhi, United Provinces, Punjab, Madras, Coorg, Bombay and Ajmer-Merwara all show an increased percentage of primary successes, the first leading with 99.66 per cent. (99.65 in 1925-26). As in the previous year, re-vaccination showed a gratifying increase from 3,331,447 in 1925-26 to 3,629,598 in 1926-27, while its success rate rose in Assam, United Provinces, Punjab, North-West Frontier Province, Coorg and Ajmer-Merwara. The small-pox mortality increased from 85,986 in 1925 to 117,066 in 1926; Bihar and Orissa alone accounting for an increase of 20,491, followed by Punjab with an increase of 10,557. The average cost of each successful operation increased slightly; that in Bombay is still more than double the cost in any other province except Burma.

ANNUAL REPORT ON THE ADMINISTRATION OF JAILS OF THE BENGAL PRESIDENCY. 1927. BY LT.-COL., W. G. HAMILTON, I.M.S. INSPECTOR-GENERAL OF PRISONS. BENGAL. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1928. PRICE, Rs. 4 OR 6s. 9d. NET.

The number of convicts on the 1st January was 10,368, against 9,982 in 1926; 23,970 were imprisoned during the year 1927, against 21,834 in the previous year, and 416 were received by transfer from other provinces.

Convicts were disposed of as follows: 705 were released on appeal; 16,302 on expiry

of sentence, 5,678 under remission rules, 136 by order of Government, 206 were transported beyond the seas, 23 were transferred to mental hospitals, 4 remained uncaptured out of those who escaped during the year, 7 were executed and 167 died. The number remaining at the end of the year and the daily average number for the year was 10,916 and 10,875.27, against 10,341 and 10,181.47 in 1926.

The average number of European prisoners was 30.03 against 47.67 during the previous year.

Transportation of convicts.—During the year 1927, 205 convicts were deported to Port Blair. These include 145 convicts transferred from the Punjab, 40 from the Central Provinces, 12 from the United Provinces, 7 from Bengal and 1 from the Bombay Presidency. The 7 convicts deported from Bengal volunteered as colonists. Seventy-three transportation convicts were repatriated from the Andamans on medical grounds, of whom three died during the year against one in the previous year.

Religion.—Of the 23,970 convicts admitted during the year, 56.29 per cent. were Muhammadans, 40.45 per cent. Hindus, 0.67 per cent. Christians, 0.92 per cent. Buddhists and Jains, 1.67 per cent. belong to all other classes against 56.06, 40.68, 0.76, 1.30 and 1.20 per cent. respectively in the previous year.

Age.—The number of convicts of less than 16 years of age admitted was 335 (329 males and 6 females) or 1.40 per cent. of the total of all classes of convicts, against 240 or 1.09 per cent. in 1926.

It is a matter of great regret that there has again been a considerable rise in the admission of juvenile prisoners during the year under notice as compared with the figures of the preceding two years, which stood at 240 and 128, respectively. This is partly due to the admission of many young boys as Satyagrahis at Patuakhali Sub-Jail where 153 were admitted during the year. The extension of the Children Act to the whole Presidency is an urgent necessity, until that is done young children will be committed to prison.

The percentage of convicts admitted from 16 to 18 years was 3.51, 19 to 21 years of age 9.61, 22 to 30 years 42.70, 31 to 40 years 28.85 and above 40 years 14.33 against 3.92, 7.82, 39.63, 28.55 and 18.99, respectively, in the previous year. It will thus be seen that the greatest tendency to crime falls between the ages of 22 and 30 years.

Education.—The number of convicts able to read and write was 10.49 per cent., able to read only 2.35 per cent., and illiterate 87.16 per cent.

Female convicts.—Direct admission from Court was 482 against 420 in 1926. Of these 217 were Hindus, 143 Muhammadans, 13 Christians and 109 belonging to all other classes. Six were under 16 years of age, 10—16 to 18, 28—19 to 21, 216—22 to 30, 129—31 to 40, and 93 over 40 years old. Here, again, we find the greatest tendency to crime to fall between the ages of 22 and 30 years. Twelve were able to read and write, 1 able to read only, and 469 illiterate; 240 were married, 4 unmarried, 175 widows and 63 prostitutes; 2 female convicts died during the year against 1 in the previous year. The daily average number for the year was 103.95 against 103.32 in 1926.

Juvenile crime.—The daily average strength of the Juvenile Jail fell from 185.36 (28.54 under-trials and 156.82 convicts) to 83.27 (1.26 under-trials and 82.01 convicts). The fall in the average number of convicts was due to the fact that the jail was emptied of its convicts when the Reformatory School was started, and that boys convicted under the Bengal Children Act were admitted to the Reformatory School. The fall in the number of under-trials is due to the enforcement of the Bengal Children Act in Calcutta and its suburbs, the accused being detained in Remand Homes.

The Reformatory School and the Industrial School which was started in July in the Juvenile Jail were transferred to the control of the Education Department from 1st April, 1928, the Jail being abolished from that date.

As usual moral and religious instructions were imparted and all reasonable facilities were allowed to the prisoners to observe their religious practices.

Regular physical training and exercises were imparted to the boys and football, badminton and other games were regularly played.

Technical instruction in such trades and crafts as tailoring, carpentry, blacksmith's work, weaving and gardening was given to make the boys self-supporting after their release.

Civil Prisoners.—Twelve such prisoners remained in jails on the 1st January, 1927, and 334 prisoners were received during the year, making a total of 346 prisoners, of whom 326 were released, leaving a balance of 20. There were no escapes or deaths among these prisoners. The daily average number for the year was 21.16 against 17.00 in the preceding year. There was a marked increase in the number admitted during the year.

State prisoners.—The number remaining at the beginning of the year was 6 and 17 were received during the year, either direct or by transfer from other jails, making a total of 23. Of these 22 were released or transferred, leaving a balance of 1 at the close of the year. There were no escapes or deaths among these prisoners. The daily average number for the year was 2.48. These prisoners are treated in accordance with the rules specially made by Government for their treatment.

Detenus.—This class of prisoners is detained under the provisions of the Bengal Criminal Law Amendment Act, 1925. Under the orders of Government they are excluded from jail statistics. There were 4 such detenus at the end of the year. The rules for their treatment are the same as those for State prisoners.

Jail buildings.—The amount expended on jail buildings during the year was Rs. 9,29,521 for original works and Rs. 2,34,247 for repairs. The main items of expenditure were the following projects: purchasing the site of the Army Clothing Storage Department; structural alterations in the Alipore Juvenile Jail.

Warder Guard.—It is very difficult to get suitable recruits and the Circle Jails find it increasingly difficult to fill up existing vacancies. The question of improving the pay and other conditions of the warder service has long been pending.

It is also essential to give warders some preliminary training before they are placed in charge of prisoners. It is ludicrous to expect intelligent work from men who have had no instruction in their duties. Under present conditions the force is so understaffed that it is impossible to find time for any preliminary training.

Escapes and recaptures.—During the year there were 16 escapes among convicts, 7 from inside and 9 from outside the jails; 12 of them were recaptured before the close of the year. Of the 9 escapes from outside the jails, 4 were from gardens, viz., 2 from the Presidency Jail and 1 each from Midnapore Central Jail and Rangpur Jail and 5 while engaged in extramural labour, viz., one each from Jessore Jail and Tamluk, Jangipur, Bongaon and Kishoreganj Sub-Jails.

In the Alipore Reformatory School, one Reformatory boy escaped through the lines of a Reformatory School.

The total number of offences committed was 26,779 against 18,376 in 1926. The number of punishments inflicted during the year was 26,779.

It will be noticed that the number of punishments inflicted on prisoners during the past year has shown a marked increase, particularly with offences connected with work and with prohibited articles; this looks as if stricter supervision has been exercised and that a higher standard of discipline has been enforced in the Central Jails.

Corporal punishment.—The following gives particulars regarding the corporal punishments inflicted during the year prepared in accordance with the Government of India, Home Department, letter No. 142, dated the 24th September, 1919:—

(1) Daily average number of male prisoners for the year 1927—10,558.22.

- (2) Total number of jail offences—23,046.
(3) Total number of prisoners punished by whipping—15.

The ratio of whipping to total number of punishment was 0.04 against 0.02 in 1926. In 20 jails there was no corporal punishment.

The number of convicts released under the remission rules was 5,703, against 5,195 in the previous year.

Financial.—The cost of guarding and maintaining prisoners in jails and subsidiary jails of the Presidency, including the cost of general supervision amounted to Rs. 25,09,958 against Rs. 23,82,569 in 1926.

The daily average number of convicts under sentence of labour increased from 9,601.58 to 10,736.75 this year. The average number of sick, convalescent and infirm and the number not employed for other reasons were 409.29, 194.80 and 437.21, respectively, and the balance available for work was 9,695.45 against 8,673.83 in 1926.

Accommodation.—Excluding hospital and observation cells, the Central and District Jails have accommodation for 10,883 male and 400 female convicts, 1,143 male and 14 female under-trials and 141 civil prisoners. Excluding the sick in these jails, the average population was 10,204.56 convicts, of which 10,105.32 were males and 98.24 females, under-trials 1,461.29 males and 20.22 females, 20.62 civil prisoners and 2.44 State prisoners.

Statement No. XIV.—The daily average strength for the year was 13,536.13, the number admitted to hospitals 12,952, and the daily average number of sick 439.73, against 12,771.80, 11,737 and 402.17, respectively, in 1926. The total number of deaths during the year was 197 against 175 in the previous year.

SICKNESS AND MORTALITY.

The death rate in 1927 was 14.5 which is slightly higher than that of the previous year, which was 13.7. Although the rate is higher than the two previous years, it is lower than it was for several years before 1924.

Cholera.—There was one case of cholera in the Alipore Central Jail and one death during the year under report, against 2 cases in the previous year, but no deaths.

Dysentery.—There were 526 admissions and 14 deaths from this disease, against 421 cases and 14 deaths in the previous year. Although the number of admissions showed a marked rise as compared with that of the previous year, the number of deaths remained stationary. Comilla had the largest number of cases (139 against 47 in 1926). Barisal had only 5 cases, against 81, 214 and 6 in 1924, 1925 and 1926, respectively. It is gratifying to note the excellent result maintained in the Barisal Jail during the year under report. The incidence and mortality of the disease have been steadily kept down in this jail since 1926. Other jails showing high admission rates were Dinajpur (80), Jalpaiguri (40) and Rangpur (37).

Malaria.—There were 3,080 cases and 16 deaths, against 2,920 and 10, respectively, in 1926. Anti-malarial measures are carried out in most districts where malaria is prevalent. Midnapore, Faridpur, Rajshahi, Alipore, Burdwan and Rangpur all show high admission rates.

Pulmonary tuberculosis.—There were 133 admissions and 32 deaths, against 124 and 25, respectively, in the previous year. Suitable cases were treated in the two special jail hospitals, viz., at Suri for Western Bengal prisoners and Comilla for Eastern and Northern Bengal prisoners.

The mortality from this disease is very high in our jails. The great majority of cases are already infected on their admission to jail.

Pneumonia.—There were 82 cases and 19 deaths against 93 cases and 17 deaths in 1926.

Healthy and unhealthy jails.—The jails with lowest death rates were Berhampore (6.59 per mille), Bankura (6.64), Midnapore (8.31), Pabna (8.38), Bogra (8.49), Hooghly (8.53) and Presidency (Indian) (9.73). The jails with the highest death rates were Rangpur

(48.34), Darjeeling (35.29), Jalpaiguri (31.14) and Khulna (31.08).

Religious instruction.—As usual, prisoners were given reasonable facilities to observe their religious practices in jails and honorary religious instructors visited the jails regularly.

Correspondence.

THE POSITION OF THE INDIAN MEDICAL COUNCILS TO THE GENERAL MEDICAL COUNCIL OF LONDON AND THE STATUS OF BRITISH ENGLISH MEDICAL DEGREES AND DIPLOMAS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I shall feel much obliged if you, or the readers of your esteemed journal, will give their views on the following subject which greatly concerns the medical profession in general.

What is the status of the qualifications of L. S. A. (London), L. A. H. (Dublin), and the licentiates and memberships of the Royal Colleges compared to the M. B. of the Indian Universities and membership licences of the College of Physicians and Surgeons, Bombay, of the State Medical Faculty of Bengal and other Indian medical licensing boards?

Whether qualifications obtained in Europe which are registrable in the British Medical Register of the General Medical Council are considered in their value and status, superior, equal or inferior to the Indian University medical degrees and membership diplomas of the College of Physicians and Surgeons, Bombay and of the State Medical Faculty of Bengal, for the purposes of naval, military and higher grade, state or public, appointments?

As far as I am aware up to the time of writing, all the regular degrees and diplomas of the English, Scotch, and Irish boards and examining bodies are registrable in the British Medical Register. This means they comply with the requirements of the General Medical Council—which is constituted of representatives from all the teaching bodies. The holders of them are equally eligible for all appointments, though special appointments are open to those who hold special qualifications.

Regarding India, the degrees of Bombay, Calcutta, Madras, Lahore, Lucknow, Colombo, Singapore are registrable in the British Medical Register, though recognition of Calcutta University was temporarily withdrawn. No recognition to membership licences of the College of Physicians and Surgeons, Bombay or State Medical Faculty of Bengal has been accorded for the purposes of registration in the British Medical Register.

This means that the General Medical Council accords recognition for the purposes of registration to those Indian degrees and diplomas whose courses are equivalent to theirs. Since no recognition till now has been accorded to Indian membership licences, which are considered here to be higher than the ordinary Indian licences, it means of course that their curriculum does not fulfil the present requirements of the General Medical Council. It is possible that at some future date recognition may be accorded, if necessary improvements are complied with.

The commission in the Indian Medical Service (temporary) has been given to those who have passed the membership examination of the College of Physicians and Surgeons, Bombay and of the State Medical Faculty Bengal, and such officers have been given higher civil appointments.

Many of the past and the present permanent officers in the Indian Medical Service with their home qualifications of L. S. A. (London), L. A. H. (Dublin), and Licences of Royal Colleges, obtained commissions, and higher colonial and civil appointments. Does this

mean that their qualifications are superior, equal, or uncomparable?

The reply by the Indian Medical Council (Bombay) is not clear, hence I am seeking the hospitality of your columns as the matter concerns all the medical institutions.

The position of the Indian Medical Councils with the General Medical Council of Great Britain is, I believe, independent and not subordinate, but nevertheless they adopt and adhere to the rulings of that body. What does this signify to their relativity? It is now for the General Medical Council of Great Britain to assert their authority and show the rightful right.—Yours, etc.

K. M. HIRANANDANY, Ex.M.P.
(Dublin).

HYDERABAD, K. J. ROAD, SIND.

NIGHT-BLINDNESS AND ITS SPEEDY CURE WITH LIVER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your August number, I have just read Dr. J. M. Richardson's letter regarding night-blindness and its speedy cure under treatment with liver. Obviously, there are cases of functional night-blindness in which there are no ophthalmic changes and which are the result merely of defective nutrition, anæmia, ill-health, etc. The rapid improvement under liver treatment is not, therefore, surprising while conversely, failure of treatment with cod-liver oil is also not surprising, as it is a truism that only certain brands of this are of any medical value.—Yours, etc.

B. J. BOUCHÉ, M.R.C.S. (Eng.), L.R.C.P.
(Lond.), I.M.D.

B. M. HOSPITAL, DINAPORE.
25th December, 1928.

TREATMENT OF GONORRHOEA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Recently I treated 2 cases of acute gonorrhœa by irrigation with warm E. C. lotion, 1 in 20. I used a douche can and Janet pattern glass nozzle. The irrigation was carried out thrice daily after micturition. An alkali mixture was given by the mouth to keep the urine alkaline. The result was magical; all urethral discharge in each case was stopped after 24 and 48 hours, respectively.—Yours, etc.,

7th January, 1929.

AURICULAR FIBRILLATION AFTER ASPIRIN.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was very interested to read of the case of auricular fibrillation brought on as a result of taking acetylsalicylic acid reported by Dr. A. K. Dutt Gupta in the September issue of the *Gazette*.

The interest is intensified because it seems to confirm the value of the formula

$$F = \frac{P + I}{S + T}$$

where F = fibrillation or failure
P = blood-pressure
I = impulses, nervous or otherwise
S = support of heart afforded by the pericardium
T = tone of muscle.

The support of the pericardium is due to the negative pressure in the pericardial cavity which I have shown is present in health. This negative pressure causes a suction action which keeps the pericardium right up against the heart save for the thin layer of pericardial fluid so necessary for lubrication. F varies directly with the pressure or nervous impulses, i.e., the greater the pressure the greater the tendency to failure or fibrillation. On the other hand, the greater the support, the less the tendency to failure.

The normal negative pressure and pericardial fluid depend on the normal healthy exudation which takes place through the coronary vessels, and any variation of this exudation tends to modify the support of the heart.

If we apply the formula it will be seen that though the blood-pressure P remains constant, yet because S the support is diminished, it follows that the tendency to F (fibrillation) is increased.

The acetylsalicylic acid evidently disturbed the exudation into the pericardial cavity and so modified the pericardial support.

Further details of my formula will be found in the *New York Medical Journal and Record* for 21st March, 1928, as well as in the *Medical Press and Circular* for 1st February, 1928, and the *Lancet*, 1st September, 1928.—Yours, etc.,

G. ARBOUR STEPHENS,
Consulting Cardiologist,
King Edward VII Welsh National
Memorial Association.

SWANSEA,
31st December, 1928.

Service Notes.

APPOINTMENTS AND TRANSFERS.

ON return from leave, Lieut.-Colonel Sir Frank Powell Connor, Kt., D.S.O., F.R.C.S., I.M.S., was reposted as Professor of Surgery, Medical College, and Surgeon to the Medical College Hospitals, with effect from the 16th December, 1928.

Lieut.-Colonel W. D. Ritchie, M.B., I.M.S., Civil Surgeon, Darrang, is appointed to officiate as Inspector-General of Civil Hospitals and Prisons, Assam, during the absence on leave of Colonel Hutcheson.

Lieut.-Colonel Sir L. Rogers, Kt., C.I.E., M.D., F.R.S., F.R.C.P., F.R.C.S., I.M.S. (Retired), is granted the temporary rank of Major-General whilst Medical Adviser to the Secretary of State for India and President of the India Office Medical Board, 3rd November, 1928.

On being relieved of his appointment as Professor of Surgery, Medical College, and Surgeon to the Medical College Hospitals, Lieut.-Colonel H. B. Steen, M.D., I.M.S., was appointed to act as Professor of Clinical and Operative Surgery, Medical College, and Surgeon to the Medical College Hospitals, with effect from the 16th December, 1928.

On return from leave, Lieut.-Colonel R. F. Steel, M.B., B.Ch. (Dub.), F.R.C.S.E., I.M.S., to be Civil Surgeon and Superintendent, B. J. Medical School, Poona.

On return from leave Lieut.-Colonel K. G. Gharpurey, L.R.C.P. & S. (Edin.), L.F.P. & S. (Glas.), I.M.S., to officiate as Civil Surgeon, Nasik.

Major H. S. Anand, M.B., Ch.B., D.P.H., I.M.S., is appointed to act as Health Officer, Simla, with effect from the date on which he assumes charge of his duties.

Major M. G. Bhandari, I.M.S., on return to duty in the Bombay Presidency, to be Superintendent and Medical Officer, Ahmedabad Central Prison.

Major B. Z. Shah, M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., Officiating Civil Surgeon, Nasik, is appointed Civil Surgeon, Belgaum, on relief by Lieut.-Colonel K. G. Gharpurey, I.M.S.

His Excellency the Governor of Bombay is pleased to make the following appointment on his Personal Staff with effect from the afternoon of 8th December, 1928:—

Major D. C. Scott, O.B.E., R.A.M.C., to be Surgeon.

Major R. M. Kharegat, I.M.S., Medical Officer and ex-Officio Vice-Consul, Sistan, on return from leave, resumed charge of his appointment with effect from the 12th December, 1928.

Major C. M. Plumptre, M.R.C.S. (Eng.), L.R.C.P. (Lond.), F.R.C.S.E., I.M.S., to officiate as Presidency Surgeon, Bombay, and Physician on the staff at St. George's Hospital, and Marine Surgeon, and in Medical charge of House of Correction, Byculia, and Arthur Road Jail, Bombay, vice Lieut.-Colonel A. N. Thomas, D.S.O., M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., proceeding on leave.

The services of Captain R. N. Bhandari, I.M.S., are placed temporarily at the disposal of the Government of the United Provinces for employment in the Jail Department with effect from the date on which he assumes charge of his duties.

The services of Captain C. L. Pasricha, M.B., I.M.S., are placed temporarily at the disposal of the Government of Bengal with effect from the date on which he assumes charge of his duties in civil employ in that province.

LEAVE.

Major-General R. W. Anthony, M.B., C.M., F.R.C.S.E., I.M.S., Surgeon-General with the Government of Bombay, is granted leave on average pay for two months and three days combined with leave on half average pay for five months and twenty-eight days with effect from the 4th March, 1929, or any subsequent date from which he may avail himself of it.

Colonel R. F. Baird, I.M.S., Inspector-General of Civil Hospitals, United Provinces, leave for six months and five days, with effect from 11th March, 1929.

Colonel G. Hutcheson, M.B., I.M.S., Inspector-General of Civil Hospitals and Prisons, Assam, is granted leave for five months and three days combined with leave for two months and twenty-seven days, with effect from the 1st April, 1929, or any subsequent date from which he may avail himself of it.

Lieut.-Colonel S. S. Vazifdar, I.M.S., Superintendent, J. J. Hospital, Bombay, is granted leave for eight months with effect from the 15th April, 1929, or date of availing.

Lieut.-Colonel H. Stott, I.M.S., Professor of Pathology, King George's Medical College, Lucknow, leave for three months with effect from 1st August, 1929, in continuation of the three months' College vacation commencing from 1st May, 1929.

Lieut.-Colonel J. Cunningham, C.I.E., M.D., I.M.S., Offg. Director, Central Research Institute, Kasauli, is granted leave for 8 months with effect from the 1st February, 1929.

PROMOTIONS.

Lieut.-Colonel F. P. Mackie, O.B.E., M.D., F.R.C.P., F.R.C.S., D.P.H., I.M.S., is appointed to officiate as Surgeon-General with the Government of Bombay during the absence of Major-General Anthony.

CAPTAIN TO BE MAJOR.

Harold Williamson, O.B.E., M.D., F.R.C.S.E., 17th December, 1928.

The provisional promotion of the undermentioned officer to the rank of Captain as notified in the Army

Department Notification No. 84, dated the 29th January, 1926, is confirmed, subject to His Majesty's approval:—
Cornellius Vincent Falvey.

RETIREMENTS.

Lieut.-Colonel J. Masson, I.M.S., dated 10th November, 1928.

Lieut.-Colonel M. Corry, M.B., dated 10th November, 1928.

Lieut.-Colonel J. B. D. Hunter, O.B.E., M.B., F.R.C.S.E., dated 12th December, 1928.

NOTES.

ALL-INDIA MEDICAL LICENTIATES CONFERENCE, MARCH, 1929.

It is notified that an Exhibition in Indigenous Drugs, Scientific and Sanitary Sections, Maternity and Infant Welfare is to be held at Lahore during the third week of March, 1929, in connection with the All-India Licentiates Conference.

ULTRA-VIOLET RAY IRRADIATION.

THE experimental studies showing the effect of the ultra-violet sun rays from the mercury quartz lamp have been very extensive in the last few years, and have added greatly to our knowledge of rickets and allied diseases.

Hess in his experiments with many food substances is of opinion that when these are exposed to the quartz lamp, they become protective against rickets. Milk, flour, spinach, lettuce, vegetable oils, etc., have been successfully activated by irradiation. He also proved that cholesterol, which is normally present in large quantities in the skin, is susceptible to activation, and becomes a depot for storing anti-rachitic substances.

Mellanby has suggested that the anti-rachitic effect from ultra-violet radiation of food results either from an increased vitamin content, or that vitamin becomes more active.

Schabad and Telfer have found that phosphorus and calcium play an important part in the metabolic function, and that the metabolism is influenced by the giving of cod-liver oil, causing the phosphorus in the blood to become increased in rickets, and the calcium in tetany, and that the phosphorus is increased by ultra-violet radiation.

Green-Armytage in his original article on osteomalacia, appearing in the *Indian Medical Gazette* of July, 1928, has proved by his experiments on animals that cholesterol, which is one of the unsaponifiable fractions of cod-liver oil, if irradiated, becomes anti-rachitic. Rats and dogs fed on irradiated cholesterol develop normally, while those fed with the same substance which has not been exposed to the ultra-violet rays develop rickets.

To those interested, particulars can be obtained from Messrs. Smith, Stanistreet and Company, Limited, Calcutta, who have special arrangements for irradiating food substances, including cod-liver oil and cholesterol, by the mercury quartz lamp.

THE 35TH CHEMISTS' EXHIBITION.

THE Exhibition organised by the "British and Colonial Pharmacist" was established in 1896 in London. It is one of the largest, if not the largest, and most comprehensive exhibitions of its kind in the world.

It was organised to give the practising pharmacist an opportunity every year of seeing, under one roof, all the goods he sells and the various apparatus, utensils and other requisites he uses in his profession. The management is always delighted to welcome visitors from the dominions and colonies, and such gentlemen

will be admitted on presentation of business card. The Exhibition has grown continuously and this year will be housed from 27th to 31st May, in the new Hall of the Royal Horticultural Society, Westminster, S. W. in the very heart of London, practically under the shadow of the Houses of Parliament and Westminster Abbey.

A CATALOGUE OF THE PUBLICATIONS OF BAILLIÈRE, TINDALL AND COX.

We have just received a copy of the latest catalogue dealing with publications in Medicine and Allied Sciences issued by Messrs. Baillière, Tindall and Cox, 7 and 8, Henrietta Street, Covent Garden, London, W. C. 2. The book is divided into four sections dealing, respectively, with (i) medicine (including dentistry and nursing), (ii) foods and food inspection, botany and agriculture, (iii) science and miscellaneous, and (iv) periodicals and reports.

All the latest productions of this well-known publishing house are listed and an index facilitates ready reference.

CALMETTE'S TUBERCULIN PROTECTIVE VACCINE.

Deutsche Medizinische Wochenschrift, No. 45, page 1,871.

B. C. G.

Schlossmann, Dusseldorf.

CONFERENCE of experts of the Hygiene Section of the League of Nations on Calmette's special tuberculin protective vaccine. (Paris 15—18th October, 1928.)

The committee of experts of the Hygiene Section of the League of Nations met in Paris on 15th October, 1928. The meeting lasting until 18th October, 1928, to discuss Calmette B. C. G. The conference was composed of the three sub-committees, namely, bacteriological, veterinary and clinical. The bacteriological sub-committee was uniformly of opinion that B. C. G. was an innocuous vaccine. The sub-committee of veterinary surgeons was also convinced that the vaccine was not an injurious one. The clinical sub-committee to which Schlossmann belonged came to the following decision: "It can be inferred from the available material that the administration of B. C. G. (1) to infants who have been fed on B. C. G. culture during the first ten days of life, and (2) to infants, children and adults who have had B. C. G. culture given to them subcutaneously, does not at any time give rise to a definite virulent case of tuberculosis. The protective vaccine brings about a certain degree of immunity to tuberculosis."

Schlossmann did not consider that the protective power of the serum was very great. The whole question awaits further research. There will be a second meeting on this subject in 1929.

WATSON'S MICROSCOPE RECORD.

THE September 1928 number of Watson's *Microscope Record*, which has just come to hand, contains as usual several features of interest to microscopists.

Under the heading of current microscopy, the technique of photomicrography with special reference to development of the negative is considered. A. A. C. Eliot Merlin has a useful article on "Hints to Beginners," while the Rev. Dingley P. Fuge has a short note on the diatom *Navicula viridis*. There is a description of the new circuit stage van Heurck microscope—an instrument which will appeal more especially to the expert.

The design of this microscope is on lines familiar to Watson microscopists. The tripod foot is wide and massive, ensuring the most rigid and steady support. This foot is shaped to allow easy manipulation of the illuminating apparatus at any inclination. The

instrument is supported by the tripod so that it is well balanced in all positions. The coarse adjustment is most carefully constructed and fitted, and permits rapid and exact focussing with high powers. The fine adjustment is by long lever and screw, a combination which is recognized as the very best that is made. The stage is firmly supported and is capable of complete rotation. Its rectangular motions are effected by a mechanism which long experience has shown to be reliable and responsive.

The substage has coarse and fine adjustments to enable modern illuminating devices to be employed with the greatest exactitude.

The body is large and is provided with two draw-tubes, one operated by rack and pinion, to facilitate exact adjustment of the tube length.

Whether used for critical observation or for the most difficult photomicrography, for exact micrometry or for the most precise investigations for which the microscope can be employed, Watson's Circuit Stage Van Heurck Microscope will be found fully equal to every requirement. For those who are not so exacting, but wish to have an instrument which offers every advantage for easy and comfortable manipulation, this instrument is offered as a *modèle de luxe*.

BENGAL CHEMICAL AND PHARMACEUTICAL WORKS, LTD.

MESSRS. The Bengal Chemical and Pharmaceutical Works, Ltd., Calcutta, advise us that they have made complete arrangements for the physiological standardisation of drugs. All preparations of drugs such as digitalis, strophanthus, squills, ergot, cannabis indica, aconite, etc., are standardised by carefully observing their physiological action on animals. The importance of physiological standardisation cannot be over-estimated: it is an absolute necessity for drugs whose activity cannot be estimated by chemical methods. They have a well-equipped laboratory under the charge of expert medical men for carrying out such tests and the most up-to-date methods of standardisation have been adopted. No batch of any preparation is issued before its strength is adjusted physiologically and a certificate of activity is obtained. All preparations are made in strict conformity with the requirements laid down in the British Pharmacopœia, and only carefully selected drugs are used.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

ON A RECENT OUTBREAK OF EPIDEMIC DROPSY IN THE DISTRICT OF BIRBHUM.

BY KALI GATI BANERJEE, M.B.,

Birbhum.

BEFORE giving details of the clinical types of epidemic dropsy observed in the recent epidemic in Birbhum, it may be pointed out that the source of the infection this year (1928) was certainly not "rice" at all. During October, November and December, 1928 the writer saw a hundred cases of beriberi in this district, and, as the evidence in this report will show,—

(i) The victims purchased rice from different sources.

(ii) Most of them used rice from their own houses and granaries, which were well protected from rain.

(iii) In one house the head of the family used sun-baked rice (*atap*), while the rest of the family were in the habit of using ordinary rice; yet the head of the family as well as some of its members went down simultaneously with the disease.

(iv) Rice from some of the infected houses was taken and stained with iodine. In every instance the absence of a uniform blue stain showed that the rice was under-milled, and the pericarp was present and not absent (*vide* Tice's *Medicine*—article on beriberi).

We do not know whether the spore-forming bacillus of *B. vulgaris* type, which has been demonstrated in infected rice by Acton and Chopra, and which is said to produce a water-soluble toxin and a neurotoxin, responsible respectively for epidemic dropsy and beriberi, can be found in any food-stuffs other than rice. But the recent epidemic in Birbhum was certainly due to the use of oil; whether the oil was infected with this bacillus or not, I cannot say, but am trying to find out.

The following facts with regard to the recent epidemic are evidence against the infected rice theory of the causation of epidemic dropsy put forward by Acton and Chopra:—

(i) The recent epidemic occurred during the winter months. Hence the view put forward by Acton and Chopra, based on the June, 1926 epidemic in Calcutta that cases are especially apt to occur during the rains, and that the incidence of the disease is liable to increase two to three weeks after exceptionally heavy rain, damaging the rice supplies, can be challenged.

(ii) Suri, and the villages of Lokpara, Vegabatipur, Kardidhya, all obtained their oil supplies from merchants in Sainthia,—the first village to become infected.

(iii) A grog merchant (J in the table) in Suri was attacked, whilst at the same time several families who were supplied from this shop were also attacked. These, however, used rice from their own homes, and not rice from the grog merchant's shop.

Possibly the causative bacillus can be cultivated from the oil used by the victims, and the outbreak had avitaminosis as its predisposing factor.

The following tests are useful in diagnosing the disease:—

(i) Reflexes. The majority of cases had lost the knee-jerk. In others it was altered. This is one of the surest tests for the disease.

(ii) Anaesthetic points were found in a few cases over the anterior surface of the tibiae. This test, however, is only occasionally positive.

(iii) Every patient felt intense pain when the calf muscles were squeezed. This "squeezing test" is most characteristic of the disease.

(iv) Squatting test. The patients are asked to squat on their heels in oriental fashion; then to stand up straight.

In some cases of the disease they are unable to stand up from the squatting position. I obtained only a few positive results with this test; possibly because the cases which I saw were early ones, which had not developed the great weakness characteristic of the later phases of the disease.

Clinical Types.

The different clinical types of the disease seen in the outbreak were as follows:—

(i) Febrile cases. In these fever generally sets in two or three days after the onset of oedema of the legs; the temperature being between 99° and 101°F. Fever generally subsided towards evening. Its presence did not seem to affect the prognosis in any way.

(ii) Dry cases. Only one such case was seen. The patient had paresis of both legs, and pain in the calves was very marked.

(iii) Gastro-intestinal type. About three-quarters of the cases started with diarrhoea, indigestion, nausea and vomiting; or else complained of bowel trouble. This was preceded by oedema of the feet.

(iv) Fulminating or cardiac cases. These cases were few. One of them had no oedema, but showed great dilatation of the heart. One schoolboy, a victim to the disease, died on the 7th day of illness from acute cardiac dilatation.

(v) Simple cases. These showed only oedema of the legs, most marked towards evening. They were generally able to carry on their duties, but a few such cases passed into one or other of the severer types described above.

The following were peculiar features of the outbreak:—

(i) Low blood-pressure and hypo-adrenia were not associated with it. Some of the patients (notably O in the table) had high blood-pressure, associated with almost total renal

failure. A certain degree of renal failure was a marked characteristic of most of the cases.

(ii) Cardiac dilatation, though marked in a few instances, was not a characteristic feature of the outbreak.

(iii) Atony of the intestine was present in only a few instances. Attention to this symptom was drawn in the Calcutta outbreak of 1926, and perhaps its absence in the Birbhum epidemic accounts for the lessened mortality as compared with the Calcutta figures.

(iv) In most patients the knee-jerks were lost or modified.

(v) In all the "squeezing test," applied to the calves, was positive.

(vi) All the patients appeared to have derived the infection from other sources than rice—probably from mustard oil.

(vii) Very few showed pigmentation of the face,—the sign of hypo-adrenia.

Treatment.

The treatment adopted was mostly dietetic. Victims of the disease, and also persons residing in the affected area, were instructed to take the following foods; germinating gram; oranges; lemons; tomatoes; raw onion leaves; cabbage leaves; unboiled milk; eggs—quarter boiled; molasses; yeast, from the date palm (palmyra tree); bread; *khichuri*, i.e., a mixture of rice and whole grain *mung* or *moosurie* boiled together; beans.

Medicinal treatment.

The following were used:—

(i) Beemax; one teaspoonful b.d. or t.d.s.; or Marmite in gr. 20 doses t.d.s.

(ii) Yeast-vimal; half a teaspoonful in hot water, was prescribed to some.

(iii) Metatone (P. D. & Co.). Two teaspoonfuls t.d.s. to neurotic and rich patients, and as an after- tonic to some others.

(iv) As a general cardiac and diuretic tonic, the following general prescription was administered (with or without modifications) to all patients.

R

Collosal calcium (Crooks' oral)	..	1 dr.
Extract punarnava liquidum	..	1 dr.
Extract arjun liquidum	..	1 dr.
Tinct. digitalis (P. D. & Co.)	..	m. 10
Liquor ammoniæ acetatis		
Liquor ammoniæ citratis	aa	1 dr.
Syrupi		
Aquam	..	aa oz. 1
		oz. i. t.d.s.

(v) Liquor adrenalin hydrochloridi, 1:1,000; in 3-minim doses b.d. was given to some patients.

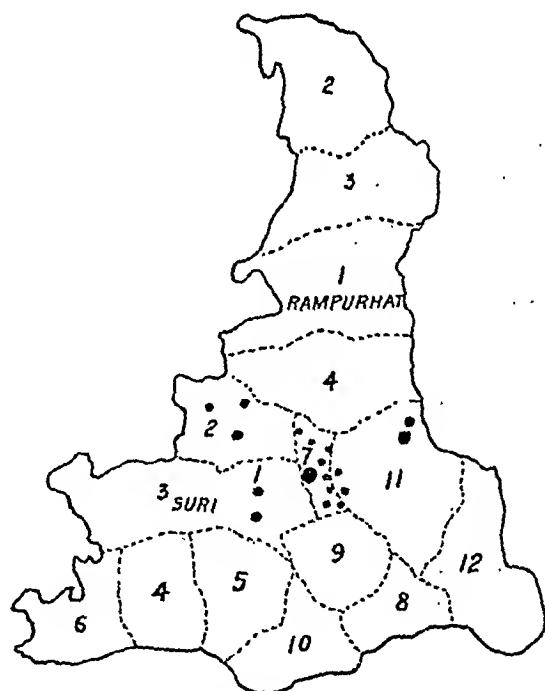

(vi) Syrup hæmogen with vitamine extract or liver extract (B. I. Co.) was prescribed in some cases to combat anæmia and asthenia.

The attached table gives details of 28 cases studied.

EPIDEMIC DROPSY IN BIRBHUM.

By U. GHOSH, M.B. (Cal.), D.P.H., D.T.M. (Bengal),
District Health Officer, Birbhum.

History.—During the middle of November, 1928, I was called in to the house of a local medical practitioner and friend of mine residing in Suri in this district, to see some members of his family suffering from œdema of the feet. I found that 8 out of the 11 members of the household were affected, including a compounder who used to take his breakfast and afternoon tea at this particular house. The rice used by the family was the parboiled and home-husked variety. The mustard oil used came from a local shop, the owner of which used to buy it at Sainthia, a junction station on the E. I. R. loop, 11 miles from Suri. At this station there is only one oil mill, and it is owned by a Marwari gentleman. On the occurrence of subsequent cases in other families in Suri, enquiries were made, and it was found that the mustard oil which they used all came from the same shop in Suri. Later, it was found that some 30 cases had occurred in Sainthia, confined to some 8 or

Black spots indicate the position of villages affected with epidemic dropsy in November and December, 1928.

Rampurhat Subdivision:	Suri (Sadar) Subdivision:

	7 & 9. Sainthia.
	8. Bolpur.
	10. Illambazar.
	11. Labpur.
	12. Nanur.

9 families; this was followed by reports of outbreaks in some 8 or 9 villages around Sainthia. The distribution of the disease is shown in the attached map.

1.	22	H.M.	No cedema.	(1) Shortness of breath on exertion. (2) Palpitation. (3) Cough. (4) Dilatation of heart. (5) Equal spacing of two sounds. ..	"	110	Constipation.	"
2.	28	M.M.	"	"	"	..	Dysentery before hand.	Knee jerks absent.	(1) Pain in both the legs. (2) Paresis of 2 legs. (3) Inability to walk.	"

Causes.—(i) Diseased Rice.—Was this outbreak due to the consumption of diseased rice, which Acton and Chopra believe to be the cause of epidemic dropsy? In no case that occurred was milled rice used; on the contrary, in two families which were affected the home-husked variety without parboiling (*ataf*) was used. The variety of rice used was in no instance more than one year in storage, and had been stored in the specially prepared and covered godown in the open space of the compound near the house.

(ii) Vitamin Deficiency.—In all cases enquired into, although it was found that there was a lack of intake of fruits or fresh vegetables (raw) in the diet, or a deficient intake of milk, yet this could not account for the epidemic, since other persons on the same diet did not contract the disease. Further, the deficiency in intake of fresh vegetables and milk is permanent among the individuals concerned, yet they did not develop epidemic dropsy previously. The theory that the persons affected were on the border line of vitamin deficiency, and that some other external or internal cause or causes precipitated the outbreak, does not seem to be tenable.

(iii) Mustard oil.—In one family at Bhagatipur it was reported that they had mixed raw mustard oil thoroughly with 3 seers of fresh goat flesh; had kept it aside for two hours, and then cooked and eaten it. Ten members of the family partook of this meal, including menials; during the night they were affected by purging and vomiting; some later developed cedema of the legs; cardiac distress ensued in one patient; and extreme weakness in others within four or five days. On making enquiries at Sainthia railway station, I learnt that the owner of the oil-mill some four months previously or so had imported 4 or 5 wagon loads of a particular seed resembling *pakra* seeds through a foreign railway. There is also another variety of seed grown locally which resembles mustard seed; it is known by the local name of *kaur* thorn seed, and yields oil on pressure. It grows wild in the jungles and does not require any special attention in cultivation. I have heard from a local man that these seeds are sometimes mixed with mustard seeds, and possibly they may be responsible for the epidemic.

Conclusion.—The consensus of opinion amongst local medical practitioners is that it was a particular batch or consignment of mustard oil which was the cause of this outbreak, and that subsequent consignments were not adulterated. That the outbreak was not due solely to deficiency of vitamin B is shown by the explosive character of the outbreak; the deficiency in vitamin B is applicable to almost all persons living in the locality, and the results of it would only have developed slowly. The rice infection theory is also not tenable, because in every instance the rice used came from the family store, and not from a common source.

TABLE.

Ingredients used for extraction of "Mustard" oil, and their prices.			
	Black variety, per maund.	Yellow variety, per maund.	
1. Mustard	.. 7-8 to 8-8	9-0 to 9-8	Cakes 3-6 without bag.
2. Soorgoocha	.. 7-4 to 7-8	Used when cheap; otherwise Sorgooj.
3. Posta	.. 13-0 to 15-0	
4. Ground nut	.. 6-8 to 7-0	Used when cheap; otherwise Sorgoocha cakes are good.

8. Kaur thorn seeds.	Not known.		

INDIAN DIETARIES IN THE UNITED PROVINCES.

By NIA NT DHAN BANERJI.

Research Worker, Physiology Department, King George's Medical College, Lucknow.

THE object which this enquiry dealt with were to ascertain, as far as possible, with regard to the dietaries actually in use in the United Provinces—

(i) their average nutritive values.

(ii) whether full monetary value is obtained for the money spent on the different articles of diet.

(iii) whether the diets concerned are suitable for the particular classes of persons who consume them; and, if not,

(iv) what should be the approximate changes in each class.

[*Note.*—As Dr. C. S. Thakur, F.C.P.S., L.M.S., Professor of Physiology, King George's Medical College, Lucknow, is of opinion that the average Indian diet is not lacking in vitamins, the vitamin aspect is not raised in this paper (1).]

The actual diets to be considered are as follows:—

(A) Average Vegetarian Diet.

Morning.

Sugar $\frac{1}{2}$ chatak.
Milk 1 chatak.
Atta $1\frac{1}{2}$ chataks.
Tea $\frac{1}{2}$ chatak in the 24 hours.
Butter $\frac{1}{2}$ chatak in the 24 hours.

Midday.

Wheat atta-rice $2\frac{1}{2}$ to 3 chataks.
Pulses 1 to 2 chataks.

Vegetables 3 to 4 chataks.
Ghee 1 to 1½ chataks.
Milk 2 to 3 chataks.
Sugar ¼ chatak.

Afternoon.

Sugar ¾ chatak.
Milk 1 chatak.
Atta ¼ to ½ chatak.
Fruits, dry or fresh.

Dinner.

Nearly the same as the midday meal, except that milk is consumed in larger quantities, i.e., about 8 chataks.

(B) Average Mixed Diet.

Morning.

Atta is less than in the previous diet, i.e., ½ to ¾ chataks.

Eggs 1 or 2.

Other articles as in Diet A.

Midday.

Fish or meat is added 1 to 2 chataks.

Pulses only ½ chatak.

Other articles as in Diet A.

Afternoon.

As in Diet A.

Dinner.

Nearly the same as the midday meal, but extra milk is consumed up to 8 chataks.

(C) Average Agricultural Vegetarian Diet.

Morning.

Gur ½ to 1 chatak.

Midday.

Atta (*bajra* and *juar*) 4 chataks.

Pulses 1 chatak.

Vegetables 1 chatak.

Dinner.

Atta (*bajra* and *juar*) 4 chataks.

Pulses 1 chatak.

Vegetables 1 chatak.

(D) Average Agricultural Mixed Diet.

Morning.

Same as C.

Midday.

Pulses ½ chatak.

Meat, fish, or eggs 1½ to 2 chataks occasionally.

Other articles as in Diet C.

Dinner.

Same as C.

(E) Mahomedan Mixed Diet.

Same as Diet B, except that the extra 8 chataks of milk are not generally consumed; instead eggs enter more into the dietary, say 2 extra eggs per day being consumed in addition to the dietary given in B above.

(F) Mahomedan Agricultural Diet.

This is the same as for his Hindu brother living on a mixed diet. I have noticed in the United Provinces and Bengal—and the same may be true of other Provinces that, generally speaking, the diets of the labouring classes of the population—especially agricultural classes—do not differ much as between Hindu and Mahomedan, but the reverse is the case with the higher caste, well-to-do classes.

Now, when it comes to comparing the protein, fat, and carbohydrate ratios in the above diets, we may draw the following observations (*vide* Table I).

TABLE I.

Comparison of diets expressed in Grams.

Class of person.	Proteins.	Fats.	Carbo-hydrates.
1. Professional man (mixed diet) Indian U.P.	117*	159	442
2. Ditto. U.S.A.	110	136	442
3. Well-to-do people Bengal.	100	150	400
4. McCay's Bengali students (7).	67*	71	548
5. McCay's Anglo-Indian	94	56	467
6. U.P. Cultivator, average.	65	19	363
7. U.P. Prisoner (McCay)	84	10	348
8. Bengal "	52	25	475
9. U.S.A. Farmer ...	101	128	476
10. Average Londoner (6)	98	60	416
11. Brickmakers, Cambridge, Mass(4).	180	365	1695
12. Voit (4)	145	100	450
13. Rubne	165	70	565
14. Playfair	185	71	568
15. Atwater	150	150	500

* The high protein value is due to vegetable proteins mostly.

A. Vegetarian Diet.

This class is consuming a useless excess of carbohydrates at the expense of proteins. One should not be led astray by the high figure given for proteins in Table I. This high figure is due to the presence of pulses (legumes) in the diet; these have a low digestibility in the human system, and—further—such indigestible proteins form a splendid culture medium for the growth of putrefactive micro-organisms. In addition to this, microscopical examination of the faeces has shown that there is a great loss of protein absorption when inferior vegetable foodstuffs are taken in(2). From observations carried out by Colonel McCay it would appear that the dal granule is the most difficult of all to break down, and that the slightest lowering of the general health is accompanied by the passage of indigested dal(3), and hence such foods are of little use in metabolism. Further, the presence of such indigestible vegetable protein residues increases the bulk of the faeces and causes disturbance of the normal digestive function by causing fermentation. The question of improving this particular diet under discussion is of great importance from an economical and sociological point of view. Our Indian leaders of thought and pioneers and intellectuals are apt to be cut off in their prime by the ravages of that canker of the intellectuals—diabetes mellitus.

One of our teachers, who has a very extensive experience of conditions in the United Provinces, is wont to impress on our minds that diabetes mellitus year by year saps the energies of a very large percentage of the judicial officers in these Provinces. One method of improving this dietary—in my opinion—would be to increase the proportion of digestible proteins by the addition of preparations of milk—such as cheese, and particularly *chana* (so extensively used in the sweetmeats of Bengal), or *maava* as it is known in the United Provinces. It is not necessary that this should be taken in the form of sweetmeats, for it can be used in the preparation of *pulaos* and of vegetables. Some Hindu families believe it to be a sin to coagulate milk by the use of rennet, or any similar ferment; but I believe that such families are few in number.

With the larger consumption of this variety of protein, and by slightly increasing the quantity of milk consumed, the carbohydrates in the form of atta and sugar should be cut down. For this class of persons a high carbohydrate value in the diet is not necessary, for the excessive carbohydrate element in the dietary is the source of a very high heat value—a value far higher than that considered necessary for a European living in a much colder climate than that of India. A bulky carbohydrate ration means increased digestive troubles, and the consequent fermentation is a source of loss of potential energy from the diet.(3) If further evidence were required that loss to the body of a very large proportion of the potential energy of the diet takes place by excessive carbohydrate fermentation, it is afforded by the practical absence of any marked tendency to the storing of fat amongst the working population of Bengal.(3)

B. Mixed average diet.

Here we observe that the protein quota is very much less, when compared with the figures of Voit, Rubner, Playfair, and Atwater, even granting that these workers were not dealing with diets under Indian conditions. By further additions in the meat, fish and eggs items, and by cutting down vegetables, the correct ratios may be obtained.

C. Vegetarian Hindu Labourer.

The plight of this class of person is very sad for he is "consuming more than his system can utilise, and more than he would normally consume if the diet were properly constituted. Deficiency diseases result from the absence of some essential element in the diet. Their occurrence is, therefore, no indication of poverty and consequent scarcity of food. "A dietary conducing to mal-nutrition may cost more than a well-balanced dietary which promotes health."(1)

The chief drawback in his diet is that the variety of protein he is consuming is of a very low grade from the point of view of digestibility. The total quantity is small, and the quantity of fat is miserably poor and entirely inadequate.

It has been calculated that an addition of 11 grams of fat to the diet enables a man to walk one and one-third miles at a slow rate.(5) To the agriculturist whose labours in the fields entail such expenditure of muscular energy the need of such a quantity of fat in his dietary is paramount. Dr. W. Burridge, Professor of Physiology, King George's Medical College, Lucknow, thinks that a large percentage of the cultivators in India get less to eat than the prisoners. Col. McCay also emphasised this fact in connection with the prisoners of Bengal. For example a prisoner gets wheat atta, while a very large percentage of the cultivators take only *bejer* and *juar* atta, which are much inferior in their nutritive composition. From the accompanying statement, very kindly furnished by the Director of Land Records, United Provinces, it will be evident that wheat is most largely grown, i.e., 17 per cent. of the cropped area of the Province, yet the cultivators cannot consume it and instead consume *bejer*, etc., which is grown only to the extent of 4 per cent. of the total cropped area.

TABLE II.

Statement showing percentages of certain crops on total cropped area for the years 1924—1928, United Provinces.

Name of crop.	PERCENTAGE OF TOTAL CROPPED AREA.			
	Years.			
	1924-25.	1925-26.	1926-27.	1927-28.
Juar ..	5	5	6	6
Bajra ..	4	4	5	4
Maize ..	4	4	4	4
Rice ..	16	18	18	17
Wheat ..	17	16	16	17
Barley ..	10	10	9	10
Small Millets, Mandwa, etc.	3	3	4	4
Gram ..	16	16	14	14
Arhar ..	4	3	4	4
Urd* ..				

* Note.—Separate figures for this crop are not available.

At present the digestibility of protein in a cereal like wheat is 67.10 per cent.(2). In future years, by a better method of cultivation and by improving the soil, a larger proportion of the protein in the food grains may be made digestible.

Conclusions.

1. The percentage of preventable mal-nutrition in this country is over 10 per cent.

2. There is a close relationship between nutritional problems and agricultural practice and conditions. The food value of the crop from the

deficiency diseases aspect; the necessity of supplementing a staple food diet by the growth or importation of foodstuffs containing the nutrient substances which the staple food lacks; the resulting necessity for cheap transport; all these are questions in which nutrition and agricultural research are inseparably linked.(1)

3. With a low protein consumption, deficient stamina, moral and physical, must be expected, (confirmed by Colonels McCay and McCarrison).

4. The present decrease in mortality is due mostly to the advances made in sanitary science and better facilities for medical relief, during the last 68 years. A further decrease in death rate is possible only by improving the diet.

5. The methods of cooking need reform, because they have a considerable influence on the digestibility of the nitrogenous constituents of foodstuffs.

6. The money spent on extra consumption of sugar, starchy food, and vegetables should be diverted to the purchase of digestible proteins.

7. "We live not upon what we eat, but upon what we digest."

I take this opportunity of thanking Dr. C. S. Thakur, Professor of Physiology, for his most valuable suggestions, and my grateful thanks are due to Mr. Anrudh Lal Mahendar, Director of Land Records, United Provinces, for giving me every possible help and kindly furnishing me with statements.

DETACHMENT OF THE RETINA. A COMPLETE CURE IN A MYOPIC CASE.

By M. D. ANKLESARIA, D.O.M.S., (Eng.), F.C.P.S., (Bomb.), M.R.C.S. (Eng.), L.R.C.P. (Lond.),
Honorary Ophthalmic Surgeon, Civil Hospital,
Ahmedabad.

THE pathogenesis of detachment of the retina is very obscure indeed, and this is particularly true for that variety of detachment which is known as primary simple idiopathic or non-traumatic detachment and which includes myopic detachments also. As a result of this, various theories have been formulated from time to time by different observers to explain why the retina gets detached from the choroid, but up to now no single one has succeeded in satisfactorily explaining its causation in the majority of cases. The pathogenesis being so obscure, it is natural that treatment of the condition, whether by medicinal or operative measures, should be equally unsatisfactory and cases of

a successful cure resulting therefrom are very rare. The majority of the cases being unaffected by treatment, or improved only temporarily, eventually become completely blind. The occurrence of even a single complete cure in an authentic case, after some definite line of treatment therefore deserves recording.

Detachment of the retina should be looked upon as a sign rather than a disease and may be due to a large variety of essentially different lesions. From a developmental point of view a weak spot exists in the anatomy of the retina. The retina develops from the ocular cup which is produced by an invagination of the apex of the primitive ocular vesicle and the cavity so produced becomes occupied by the lens vesicle. Owing to this invagination the ocular cup becomes bilaminar or composed of two layers. The outer layer is thinner and forms the pigment epithelium of the retina and the inner layer, which is much thicker and which becomes folded back, forms the rest of the layers of the retina, the two layers being everywhere in mere contact with each other, the original cavity of the ocular vesicle though potentially existing being virtually obliterated. The outer layer being reduced to a single layer becomes the pigment epithelium layer of the retina and is closely united to the choroid, while the inner layers are nowhere firmly attached except at the ora serrata and at the optic disc. Between these two attachments the retina and the choroid are merely held together by the tension of the vitreous covered over by the hyaloid membrane and by the inward prolongations of the pigment epithelium in between the rods and the cones. A weak spot thus exists in this inter-retinal space, lying between the pigment epithelium on the one hand and the other layers of the retina including the rods and the cones on the other, and a separation when it occurs, does so at this weak spot, the pigment epithelium still remaining adherent to the choroid and the space between the two being filled by serous fluid.

From a pathological point of view a detachment usually originates in two or three principal ways. In the first place the retina may be either pushed in or pressed away from its bed on the choroid into the vitreous chamber by a force greater than the tension of the vitreous, such as would occur owing to accumulation of fluid in the inter-retinal space from inflammatory conditions of the choroid or the retina, or from a new growth; or, secondly, it may be pulled inside into the vitreous chamber owing to shrinkage of the vitreous in consequence of the pressure exercised by it ceasing to act, owing to the presence in it of fibrous bands or adhesions, or due to cicatricial changes occurring in the

retina. A third form has also been described by Sir William Lister as due to a hole or holes in the retina, the retina in this case being floated in by the transposition of fluid vitreous through a hole in it. The hole may be attributed to a blow or to cystic degeneration of the retina, or to fibrous bands in the vitreous, or to choroiditis, or it may be idiopathic in nature. Though by no means a satisfactory classification, for all practical purposes detachments of the retina may be divided into two main groups (a) *simple primary idiopathic* or non-traumatic detachments, which cannot be attributed to any definite cause or any well-defined or easily recognised lesion, including the myopic ones also; and, (b) *secondary or symptomatic* ones due to some definite pathological lesion, local or general. Such cases occurring after large quantities of escape of vitreous due to an injury or an operation, and those due to early stages of an intra-ocular growth come into this category. It may also be due to such local diseases as severe exudative choroiditis or cicatricial changes in the retina, or due to a general uveitis with plenty of exudate in the vitreous or due to hæmorrhages in the vitreous, degenerations and cicatricial bands in the vitreous, which get attached on the retina and subsequently by their contraction pull upon it. Constitutional diseases such as nephritis of various forms, pregnancy, influenza, scarlet fever etc., are held responsible for its occurrence in yet another class of cases. The pathogenesis of this latter group has been fairly well understood. In cases of extensive renal retinitis or retinitis of pregnancy, where the detachment is due to a transudation of fluid from the retinal tissues into the sub-retinal space, the prognosis is not so bad, as with the improvement in the general condition of the patient, following on proper treatment, a corresponding improvement and even disappearance of the detachment has been noticed to occur every now and then. The same is true of some of the traumatic cases, where the detachment is due to a blow causing an exudation in the inter-retinal space which gets absorbed in course of time, and here also the prognosis is not so unfavourable. On the other hand, cases occur in which a rent or a tear occurs in the retina, giving free access of vitreous into the inter-retinal space. In such cases the prognosis is hopeless.

The same cannot be said, however, with regard to cases of the first group, the spontaneous or idiopathic variety of detachment, a fairly large majority of which are myopic detachments and with which we are most concerned at present. This class is usually characterised by the occurrence of the usual prodromata, by the sudden onset, by the absence of any known cause, or any other very definite involvement of other structures

in the eye. The pathogenesis of this class is very obscure from the first and the prospects of a successful cure even after treatment of a long and tedious nature are problematical.

Of the various theories that have been put forward to explain the genesis of this form of detachment of the retina perhaps the commonly accepted views are two in number: (1) the exudative theory, subsequently modified by Raehlmann and called the diffusion theory; and (2) the vitreous traction theory of Leber and Nordenson. The former maintains that an exudate forms in the inter-retinal space as a result of an effusion of fluid from the choroidal vessels, this fluid being of a more albuminous character and of higher specific gravity than the fluid of the vitreous. Side by side with this process some degenerative changes occur in the vitreous, probably as a result of deficient secretion from the ciliary body. The normal vitreous loses its jelly-like structure, its supporting framework and the hyaloid membrane covering it shrink, floating opacities develop in it, it becomes more fluid in consistence and the empty space between it and the retina becomes filled with free fluid derived from the ciliary processes. The general lowering of the vitreous tension causes passive hyperæmia in the choroidal vessels and would upset the balance and cause an inter-retinal transudation to form, which would push the retina out of its bed from the choroid inwards, a corresponding escape of fluid vitreous occurring through the anterior chamber and excreted through the filtration angle without any rise in the intra-ocular tension occurring. This theory fails to explain satisfactorily why these exudates and the detachments are more frequently located in the upper part of the fundus than in the lower part, and why the exudation remains localised there to the extent of causing a detachment rather than spreading to the neighbouring parts, and also owing to the rapidity of its formation why the intra-ocular tension does not get increased as one would expect to find in the ordinary course of events. The modified diffusion theory of Raehlmann presupposes three essential conditions; firstly, vitreous of low tonicity, i.e., more fluid than normal; secondly, a choroidal or a retinal lesion giving rise to an inter-retinal exudate of a high albuminous character, higher specific gravity and lesser saline constituents; and, thirdly, an active membrane such as the retina is. What follows as a sequence of the conditions mentioned is that owing to abnormal osmotic pressure in accordance with the laws of diffusion a flow of saline fluid would occur from the higher-content salines contained in the vitreous into the sub-retinal exudate which would swell up the retina and causing pressure upon it would rupture it, that is, a rupture occurs after the retina is detached.

To understand the occurrence of these events let us recall to mind the series of changes that occur in the eyeball as a result of myopia of fairly high degrees. Detachments occur more readily in myopic eyes than those due to other conditions (Galezowski found that out of 1,158 cases of detachment 918 were in myopic eyes; Uhthoff found that myopia was the cause in 61 per cent. of his series). The cubical capacity of the scleral cavity becomes increased in myopia, due to distension of the posterior pole of the eyeball, when of fairly high degree as from 8 to 12 dioptries and upwards. With this increase there is no corresponding increase in the size or in the growth of the choroid or the retina except by way of stretching or retraction as it occurs round the optic disc, nor is there any corresponding increase or growth of the normal vitreous.

The elongation of the eyeball thus occasioned causes some interference in the natural cohesion existing between the pigment epithelium and the other layers of the retina, giving rise to some stretching and exudation in this inter-retinal space. Consequent upon this and upon nutritional disorders in the uvea, the supporting framework of the vitreous becomes broken down. This causes increased fluidity, secondary degeneration and floating opacities in the vitreous, due to the breaking up of the delicate fibrillæ which form its matrix, and reduces its tonicity below par and so the first essential condition predisposing to a detachment is obtained in myopia. The second essential factor is a sub-retinal exudate which also sometimes results from an equatorial choroiditis, but more frequently in virtually healthy myopic eyes from a venous stasis or from circulatory disturbances in the uvea, to which these eyes are particularly vulnerable. Add on the top of this some form of trauma as sudden physical exertion or fits of coughing, vomiting, lifting of heavy weights, a fall on the body, a blow on the face or the head, or any such condition becoming the exciting cause, may bring about an increase in the venous stasis existing in the eye or in the chorio-capillaries, and it is conceivable how a small sub-retinal exudate or a hæmorrhage may occur, which might eventually lead to a detachment, as explained by Raehlmann. Any local or systemic affection involving the ciliary body or the choroid which are the principal nutrient coats of the eye may further predispose to its occurrence.

The second theory is that of Leber-Nordenson and it is also known as the vitreous traction theory. Its assumption is based on the facts that as a result of chronic inflammatory disorders in the uveal tract exudates form in the vitreous, which loses its normal jelly-like consistence and cause adhesions between the retina and the vitreous at

places other than the normal attachments, viz., the optic disc and the ora serrata. The supporting framework or the stroma of the vitreous shrinks along with the hyaloid, fluid accumulates in the meshes of the fibrillæ, these latter also shrink and sub-retinal fluid is found to fill up the gap so caused between the hyaloid and the retina. Later on as a result of shrinkage of the vitreous, the retina is pulled upon either at its normal attachments, i.e., at the optic disc, and at the ora serrata, or the exudates may form false attachments which may be pulled upon and eventually a tear may be caused in it and a detachment may occur. The intra-ocular tension is usually diminished in such cases. This theory presupposes three essential conditions, a degeneration of the vitreous with coarse fibrillation, contraction of the fibrillæ and liquefaction of its substance, pulling upon the retinal or the false attachments; finally, a tear and lastly a detachment may occur. Leber further maintains that the epithelial cells of the pars ciliaris proliferate and may grow into the inner surface of the retina and thence migrate into the vitreous, their passage being facilitated by degenerative changes occurring in it, and the epithelial cells there undergo connective tissue changes and form membranes limited to the inner surface of the retina at its posterior part. These changes cause compression and in course of time condensation of the vitreous, and adhesions between it and the retina may also occur. Later on perforation of the retina may take place due to the traction exerted on it by the contraction of the newly formed membranes, the latter circumstance being aggravated by movements of the eyeball. In myopic eyes it has been found that delicate membranes form on the inner surface of the retina and consequent on the traction exerted on the retina a tear and a detachment may develop. The essential fact common to both these theories is fluidity and degeneration of the vitreous which is a *sine qua non*, for with a healthy vitreous detachment is extremely rare.

Gonin in a valuable contribution presented to La Societe d'Ophthalmologie on the pathogenesis of *idiopathic* detachment of the retina holds views more or less similar to those held by Leber. He maintains that a tear or a rupture in the retina is a more common occurrence than it is supposed to be, and that the detachment is essentially due to a contraction of the vitreous owing to the presence in it of strands of epithelial cells undergoing proliferation and connective tissue changes, and not to newly formed membranes on the inner surface of the retina as explained by Leber. The way in which this is brought about is explained by supposing that owing to nutritional disorders in the

anterior uvea an atrophy of the ciliary body occurs, its epithelial cells proliferate and migrate into the vitreous, their passage being facilitated by degenerative changes occurring in it and there they undergo connective tissue changes which cause condensation of the vitreous and adhesions between it and the retina. A perforation of the latter occurs, due to the traction exerted on it, and aggravated by movements of the eyeball. As an exciting cause a sudden blow on the face or a jerk or some sudden physical exertion may so displace the intra-ocular contents that the traction may be aggravated and eventually a tear may occur. Myopic eyes are more vulnerable to such circulatory disturbances in the anterior uvea and are thus predisposed. Gonin further explains certain peculiarities which occur, however, with regard to the origin, the onset and the appearances of a detachment. The onset is as a rule sudden, but there may be some prodromata such as floating spots or photopsæ, flickering of light, or sparks in front of the eye or some form of metamorphopsæ. This phenomenon is usually followed by the sudden appearance of a dark web or veil or a cloud coming in front of the eye and localised to a particular area to which the detachment is confined. Detachments occurring in the upper part of the fundus are relatively more common than those occurring in the lower part and are usually of sudden onset, appear as a bulging sac in the retina and are frequently accompanied by a tear or a rupture of the retina. Those starting in the lower part of the eye are usually of slow development, are not so bulging but flat in appearance, they remain localised to the area involved and are seldom accompanied by tears or ruptures. In cases of recent detachment, a cloudiness or an opacity of the vitreous may be seen in the neighbourhood of the detachment, usually accompanied by a tear situated in the periphery, and the details of the papilla in the centre may appear hazy, and in later stages floating opacities may be seen. When a detachment is of recent origin and can be taken in hand immediately, there is the possibility of a cure resulting in the complete sense of the term both as regards function and appearance. In other cases the detachment may settle down to the lower part of the fundus and spare the macula and fairly useful vision may remain for a pretty long time, a few such cases occurring every now and then.

Dealing with the prognosis of detachment of the retina, in a most complete and masterly review of this subject Ernest Thomson cites numerous figures of cures of a spontaneous nature, as well as after various forms of treatment by different observers, and submitting the figures to a most elaborate and critical analysis, summarises his conclu-

sions, putting down the percentage of spontaneous cures at 7.2 and that after all other forms of mixed treatment at 10 per cent. Against this may be mentioned the fact that in May 1912 Vail of Cincinnati, Ohio, addressed a circular letter to 460 leading oculists from all large cities of the United States, enquiring:—

(a) How many cases of non-traumatic detachment of the retina have permanently cured?

(b) What was your treatment?

Two hundred and eighty-one replies were received in all and out of these 250 reported that they had never cured a single case, though temporary improvement was noticed in many instances. Thirty-one oculists reported having cured 41 cases in all, 25 having cured one case each, 4 had two cures and 2 had 4 cures each. In two of these cured cases the detachment was due to the albuminuria of pregnancy, which cannot be included in this series, leaving in all 39 cases of cure ultimately secured after having employed every known line of treatment. In about half of this number the cure was not convincing from the records submitted, leaving in all about 20 cases of cure. Hence Vail concludes that the prospects of a cure are reduced to less than 1 out of 1000. This is an unnecessarily pessimistic and low figure. An interesting report was published in 1916 by the Committee appointed by the Ophthalmoscopic Society of the United Kingdom to report upon the cure of detachment of the retina. A case was accepted as cured if the retina became reattached and remained so for a period of not less than six months, irrespective of the restoration of proper function or the visual result. In all 85 cured cases were reviewed, and a large majority of them—51—had myopia as an ætiological factor. A haze or cobweb opacities were reported in many of these cases. In 44 cases recovery was attributed to some form of operative interference; in 24 cases recovery was spontaneous; and in 17 cases was due to non-operative treatment, in which rest in bed and the use of a pressure bandage played an important part.

The following is an interesting case of a detachment of the retina in a myopic eye, in which a definite line of treatment was adopted with complete rest in bed, which resulted in a complete cure of the detachment both as regards appearance and function:—

History.—R. D. A., age 17, son of a medical colleague, was sent to me for refraction of his eyes. Under homatropine and cocaine his refraction and correction was as follows:—

R. E. $\frac{c-7 \text{ d Sph.}}{-1 \text{ d cyl. ax. } 30 \text{ d \& out}=6/6}.$
J. 1.

L. E. $\frac{c-7 \text{ d Sph.}}{-1 \text{ d cyl. ax. } 30 \text{ d \& out}=6/6}.$

J. 1.

About 14 months afterwards he again saw me with a complaint that about three days previously while

getting up from his bed he noticed a shadow in front of his right eye which was persistent, and there was dimness of vision with it also. He said that once before he had had a similar complaint after an over-strain of the eyes, but at that time it had disappeared in a few hours. The only important part of the history was that the lad had just finished his matriculation examination and had been playing tennis for 2 or 3 hours daily for the last week or two. The vision of the right eye was reduced to 6/36 with the glasses he was wearing. The right pupil was a little more dilated than the left and the reaction to light was a little less active than in the other eye and the tension of the eye was normal. Under homatropine and cocaine a large and fairly transparent detachment of the retina was found occupying the upper and the outer quadrant of the right eye and it presented all the typical signs. The nature of the trouble was explained to the boy, and as at that time his parents were in Bombay he hastened there to obtain a second opinion on his case. The boy's father who was a medical man was also informed of the condition of the son's eye. They consulted an eye specialist in Bombay who confirmed the diagnosis and endorsed the opinion. They immediately returned home and started treatment. He was at once put to bed and complete rest, physical and physiological, was enjoined; both eyes were bandaged and subconjunctival injections of saline solution beginning with a 4 per cent. strength were given in Tenon's capsule over the site of the detachment. Each succeeding injection was increased in strength, till a 10 per cent. solution was reached which was kept up. In all about 10 such injections were given, every 3rd, 4th or 5th day, varying with the reaction the injection induced. Internally he was given urotropin grs. 7 twice daily, which is said to produce a salutary action on the secretions of the ciliary body, and a mixture containing potassium iodide, sodium salicylate, etc., with salines. After a course of treatment lasting for about a fortnight, he noticed that the dark veil in front of his eye was less conspicuous on looking about, and it gradually grew less and less, till after a rest in bed of about six weeks he found that he could see just as well as before with his glasses. An ophthalmoscopic examination of his eye was made under homatropine and cocaine and no sign of a detachment could be made out at all. He was gradually allowed more freedom to sit up and go about a little slowly. Three weeks later he had an attack of fever which turned out to be an exceptionally severe attack of typhoid fever, lasting for about 6 weeks. The patient remained in a semi-comatose condition during the last week or ten days and was kept on nasal feeding and medication, so great was the toxæmia of the typhoid attack. The prolonged period of rest in bed had evidently upset his metabolism considerably. He eventually got better, and the convalescence was uninterrupted. His eye was re-examined 11 months after the detachment under homatropine and cocaine with the correction, and his vision was as follows:—

R. E. $\frac{c-7 \text{ d Sph.}}{-1 \text{ d cyl. ax. } 30^\circ \text{ d \& out}=6/6 \text{ ptly.}}$
 J. 1.
 L. E. $\frac{c-7 \text{ d Sph.}}{-1 \text{ d cyl. ax } 30^\circ \text{ d \& out}=6/6.}$
 J. 1.

The ophthalmoscopic examination revealed no evidence whatever of a detachment and the retina was found completely re-attached and fully functioning. In fact the retina was found so firmly re-attached that such evidence as spotting of the fundus or rectilinear striations with or without pigmentation or the curved line of demarcation of a yellowish or whitish colour separating it from the healthy fundus was conspicuous by its absence. He was then allowed to continue his study in the Arts College.

From an isolated case of this nature no positive deduction can be arrived at, but the

facts are well worth bearing in mind, that a cure in the complete sense of the term can occur, though very seldom indeed, and although we are not in a position to determine what part of the success achieved was due to therapeutical measures and what part spontaneously to nature, no efforts should be spared to do all that can be done in the interest of the patient. The boy's visual acuity now, several years after the detachment, is just the same, and nearly normal in spite of the fact that he is actively pursuing his studies.

By Dr. M. J. PARMANAND, M.D. (Bom.).

(From the Adams-Wylie Memorial Hospital and Pathology Department of the Seth Gordhandas Medical College.)

THE author of this note investigated a few cases of rat-bite fever at the Adams-Wylie Hospital in the year 1922. A detailed description of the morphology of the causative spirillum and the technique employed in isolating and demonstrating the organisms was then given (Parmanand, 1923).

Most workers on this subject have recognised the difficulty of staining the flagella of *Spirillum minus*, the causative organism of rat-bite fever. Futaki (1917), the discoverer of this organism in this article says that "the flagella may or may not become stained by Giemsa's stain or silver solution". Adachi (1921) recommends fixation of the smears with methyl alcohol or osmic acid vapour and staining with Akashi's solution rendered slightly alkaline. Akashi's solution, he says, is a modification of Giemsa's stain. He further states that "it was not always possible to obtain the same staining power though the method of preparation was always the same." Mackie and McDermott (1926) however appear to have obtained satisfactory results with this method. "Staining of the flagella was only occasionally achieved" by Mooser

PLATE I.

(1924), but he was able to demonstrate them more easily by Burri's method. Robertson (1924) encountered the same difficulty and says that "for some reason the flagella are very difficult to stain and even using the same technique constant results could not be obtained." Knowles (1928) stains his specimens with Tribondeau's modification of Fontana's stain and in his experience this method brings out the terminal flagella with considerable constancy.

The presence of flagella in my strains of the organism was first noticed in specimens stained by the usual Fontana's method. Since then I have been able to demonstrate them by the Indian ink method on repeated occasions. I must here state that the only brand of ink found suitable for the purpose is "Pelican" brand Indian ink made by Gunther and Wagner. The number of successful preparations showing the organisms with flagella were very few indeed. An attempt was then made to find out a good method for staining the flagella and the following modification of Fontana's method was devised and was found to give a greater number of successful preparations than any other method:—

- (1) *Solution No. 1 (Fixative).*
 Formalin .. 20 c.c.
 Aqua distill .. 100 c.c.
- (2) *Solution No. 2 (Mordant).*
 Tannic acid .. 20 G.
 Aqua distill .. 100 c.c.
- (3) *Solution No. 3.*
 Silver nitrate .. 5 G.
 Aqua distill .. 100 c.c.

This solution is ammoniated before use till one gets a faintly opalescent fluid. The method of staining is the same as in the original Fontana method. The smears must be thin and the slides must be warmed carefully after sufficiently flooding them with solutions No. 2 and No. 3.

The smears or portions of smears in which the plasma layer has remained unruffled and do not show any tears under the microscope, contain the best specimens of the organism showing the flagella. I generally prepare a dozen smears from the blood of an infected guinea-pig and stain them by the above method and am able to get at least two or three good preparations showing the organisms with unmistakable flagella.

Recently, however, I have been using the method recommended by Coles (1926) of relief staining with a saturated aqueous solution of nigrosin. The organisms appear white against a uniformly blue background. The flagella are clearly brought out by this method of relief staining. The technique is precisely the same as in the Indian ink method, but the slides must be absolutely clean and grease free.

Some observers have occasionally come across more than one flagellum at each end. This appearance, however, is said to be produced by the fraying of the flagellum brought

about by the action of fixatives and mordants used in the various processes of staining. Futaki, Takaki, Taniguchi and Ohsumi (1917) also noted two terminal flagella in some of their preparations. But later on Futaki, Takaki, Taniguchi, Ohsumi, Ishiwara and Ohtawara (1925) concluded that this was probably due to some technical errors, and further say that "this organism has only a single long flagellum at each end of its body." Robertson (1924) observes that the appearance of multiple, flagella at each end "seems to be more the result of the fixative than a characteristic of the parasite, as in fresh specimens in which the movements have slowed it has only rarely been possible to demonstrate more than one flagellum." McDermott (1928) stained his specimens with Adachi's method and found one to seven flagella at each end of this organisms. The author of this note has occasionally encountered organisms showing two flagella at each end in films stained by the modified Fontana's method, but has never seen more than one flagellum at each end when the organisms are observed in the living condition under dark-ground illumination.

Finally several attempts were made to cultivate the organisms in Noguchi's and Joekes' media but they were all unsuccessful.

The photomicrographs were taken in the Pathology Department of the Seth Gordhandas Sunderdas Medical College, with Bausch and Lomb's cuscope with the camera attachment.

Acknowledgments.

I am grateful to Professor V. R. Khanolkar, M.D., B.Sc. (Lond.), Professor of Pathology and Bacteriology at the Seth Gordhandas Sunderdas Medical College, for giving me an opportunity to work in his Department and also for much kindness and advice. My thanks are also due to Dr. R. N. Parmanand, Medical Officer in charge of the Adams-Wylie Memorial Hospital, for giving me facilities in obtaining clinical and other material.

AN IMPROVED DROP REGULATOR.

By R. L. SPITTEL, F.R.C.S.,
Surgeon, General Hospital, Colombo.

It is, perhaps, not too much to claim that a drop regulator for controlling the flow of saline and glucose solutions in proctoclysis and of various antiseptic lotions in the continuous irrigation of septic wounds, is one of the most important pieces of apparatus a ward can possess.

In the absence of such a regulator one finds, on visiting a patient for whom, for example, continuous proctoclysis has been ordered, that the apparatus is more often than not conspicuous by its absence. On inquiry as to the reason for this one learns that "the saline has been given, but the patient has returned it." And yet his life may depend on his absorption of the fluid administered.

of the reservoir, and the other end with a glass U-tube which was hung inverted on the rim of the reservoir to permit of the escape of flatus and regurgitant fluid. But this is a very difficult method of administering adequate proctoclysis; and now the intervention of a stop-cock regulator of some sort is, I believe, more or less in universal vogue. It is certainly fool-proof and easy.

For the continuous irrigation of septic wounds too (Carrel-Dakin drip) the drop regulator is a great necessity.

There are many drop regulators on the market, such as Canny Ryall's, in which the stop-cock is part of the apparatus, or Laurie's which is solely a dropper necessitating a stop-cock on the proximal tubing. But these special apparatus have a great knack of getting easily broken, and are not readily replaceable at a pinch in remote hospitals.

Fig. 1

Fig 2

Fig. 3

Such a complaint is seldom heard when a drop regulator is in use and the visible out-flow so controlled that the drip is at its tardiest, several seconds intervening between the incidence of any two drops. Then proctoclysis can be maintained for hours on end without mishap.

Murphy, to whom we owe the idea of proctoclysis, used no stop-cock at all, but aimed at obtaining a slow drip by placing the upper level of the fluid in the reservoir just above the anal level, and connecting the rectal tube through rubber tubing with the stem of a glass Y-tube, one arm of which joined up through rubber tubing with the outlet nozzle

I write this note to call attention to the ease with which such droppers can be improvised out of materials readily obtainable anywhere. I have little doubt that this obvious device has occurred to many others as well; but I have nowhere seen it described.

The apparatus is made as follows:—Take the tapering end of a pipette, or an empty ampoule filed off at either end—preferably one thinning out both ways because it is easy to file, such as the saline ampoule of an electrargol set. This is snugly fitted into a short length of glass tubing by means of a thin rubber collar, if necessary, outside the pipette-end or ampoule (fig. 1) to make up for any

disparity between the outer and inner tubes. All that now remains to be done is to connect rubber tubing to either end of the glass tube and to provide a regulating stop-cock on the reservoir side of the dropper, as shown in fig. 2.

The same idea may be carried out with an ordinary irrigating nozzle fitted into a filed off test-tube and connected by a small piece of rubber tube where the base of the nozzle makes contact with the test-tube as in fig. 3.

There are many other simple variations of these devices which will suggest themselves according to the variety and calibre of the glass tubes available.

(Since writing the above, I have read with much interest the article by Lieut.-Col. Proctor in the January 1929 number of the *Indian Medical Gazette*.)

ANALYSIS OF A HUNDRED CASES OF CATARACT EXTRACTION AT THE RAIPUR MAIN HOSPITAL BY SMITH'S METHOD WITH A FLAP OF CONJUNCTIVA.

BY H. B. D. NANHORYA, M.B., B.S.,
Assistant Surgeon, Main Hospital, Raipur, C. P.

(A) *Preliminary*.—The routine examination of the eye to be operated on is gone through as follows:—

(a) *Lachrymal Apparatus*.—If this be diseased

SMITH WILSON'S KNIFE.

Blunt straight edge.

Sharp curved edge.

the operation is postponed till the condition is improved.

(b) *Conjunctival Sac*.—Slight mucous discharge is neglected, but if it is much and muco-purulent the eye is treated for a few days before being operated on. Irrigating the eye with boric lotion grains 10 to 1 oz. and instilling a few drops of protargol, grains 10 to 1 oz. or acriflavine 1 in 1,000 twice daily, clears up the discharge in 3 to 4 days' time.

(d) *Iris and Pupil*.—If there is no reaction or sluggish reaction of the pupil, a preliminary iridectomy is done, and in suitable cases extraction of the lens is performed after two or three months with a good useful vision.

(c) *Projection and perception of light*.—This is absent in old glaucomatous cases, which are not suitable for operation.

(f) *Tension*.—This, if on the plus side, should warn us to be more careful during the operation.

(B) *Preparation*.—The eyelashes are cut short and the patient is put on the table and 10 per cent. cocaine solution is put into the conjunctival sac thrice at intervals of five minutes each. The outside of the eye is cleaned with a cotton swab soaked in hydrarg. perchlor. lotion 1 in 4,000. Smith's eye speculum is put in and the conjunctival sac is irrigated with 1 in 5,000 solution of hydrarg. perchlor. with the irrigator at about 5 ft. height.

(C) *Operation*.—Smith Wilson's cataract knife is used here as it has an advantage over other knives. The blunt edge is straight and in the same line as the handle, while the sharp cutting edge is curved and tapers to a fine point. The advantage of this is that a minimum force is required to puncture the sclero-corneal junction because a force acts to the best advantage when applied in a straight line; since we hold the knife with the blunt edge downwards which is straight; and consequently the point of the knife is not damaged too soon.

The knife enters at 9 o'clock and emerges at 3 o'clock and with a slight to and fro movement the corneo-scleral margin is cut on both sides. The cutting edge of the knife, when it reaches 11 to 1 o'clock, is tilted a little backwards and while finishing the incision a conjunctival flap is taken up with the cornea. This flap is generally triangular in shape and can always be taken up in the incision.

The advantages of this conjunctival flap are:—

(c) *Cornea*.—In cases of old central leucoma, a peripheral iridectomy with extraction of the lens is sufficient to restore good useful vision to the patient.

(1) The margins of the wound in the cornea are satisfactorily apposed by manipulation of the flap. It sometimes happens that after the delivery of the lens, the lower margin of the wound

is sucked in to the cavity and it is difficult to have satisfactory apposition of the margins of the wound with the consequent attendant dangers. All this is obviated by means of the flap.

(2) It gives an additional support to the wound and consequently a firmer cicatrix, which is so essential with some patients who, contrary to instructions, get up and try to walk just after the operation.

(3) There is less likelihood of prolapse of the iris.

(4) It effectually shuts off any infection in the conjunctival sac; as it has been noticed even during the operation that if the flap is not turned down over the cornea it again sticks to its original place.

(5) It expedites the healing of the wound as a skin graft does in other places.

The conjunctival flap is turned down over the cornea and iridectomy is performed, care being taken not to button-hole the iris, in which case there will be a little difficulty in the delivery of the lens. The speculum is removed and the eye cleaned with a sterile cotton wool. The operator holds up the upper lid with an eyelid retractor held with the thumb, index, and middle fingers of the left hand, while the little and ring fingers of the same hand control the upper part of the orbicularis oculi. The lower part of the orbicularis is held by the assistant. A strabismus hook is held in the right hand and the lens is dislocated from its attachment by gentle semi-circular strokes just below the sclero-corneal margin. The delivery of the lens is effected by firm moderate pressure applied backwards and upwards, and changing the direction gradually upwards following up the lens till its emergence from the wound. The iris is reposed, the margins of the wound apposed and the conjunctival flap is replaced in its original position and the eyes bandaged.

(D) *After-treatment.*—Both eyes are bandaged for the first three days and the patient is instructed to lie as quietly as possible for this period. Milk is the diet for the first 24 hours and after this ordinary food is allowed. On the 4th day the eye is opened and the eye pad changed and the unoperated eye left unbandaged, the eye is now opened every alternate day and the pad changed; on the 10th day a green shade is given, and after a couple of days the patient is discharged from the hospital. No washing of the conjunctival sac is done, but the lids are just cleaned with cotton wool soaked in a weak perchloride solution.

(E) *Complications.*—(1) *Escape of Vitreous.*—This occurred in 10 cases out of the series of 100 cases. In 9 out of these 10 cases there was very slight escape, about one or two drops. In one a large quantity of vitreous escaped. This case is described subsequently.

(2) *Rupture of the capsule.*—This occurred in 4 cases, out of which in one case it could not be detected till the 4th day after operation and hence was left in. In two cases the capsule

could not be taken out, owing to adhesions, and in one case it was removed during the operation. The capsule did not interfere with the vision as it was in the periphery; in all three cases the condition was much cleared subsequently with dionin drops.

(3) *Prolapse of the iris.*—There was prolapse of the iris in one case only, to be described subsequently.

(4) *Suppuration of the eyeball.*—There was only one case, but the other eye of this same patient which was exactly in the same condition was operated on a few days later with very good results.

(5) In a solitary case as soon as the incision was finished the lens, vitreous, and iris shot out of the eyeball. The eye was at once closed and bandaged. On opening on the third day, the cornea was found turned over on itself with a prolapse of the iris and the wound gaping wide. The cornea was turned up and the conjunctival flap straightened out and the eye was again bandaged. Healing took place and there was vision in the eye, but the prolapsed iris remained under the conjunctival flap. As it is so difficult to be in touch with patients after operation we know nothing further of this case. This is the case referred to under (1) and (3).

Cases operated on, 100.

Complications.	Number.	Percentage.
Escape of vitreous ..	10, in 9 slight and in 1 large.	10
Rupture of lens capsule	4	4
Prolapse of iris	1	1
Suppuration ..	1	1

(F) *Other cases.*—(1) *With a sluggish or no reaction of the pupil.*—4 cases belonged to this category. A preliminary iridectomy was done in these cases about four months previously and the reaction returned. These were successfully operated on with good vision and no after complications.

(2) *With central corneal leucoma.*—2 cases of this nature were operated on with peripheral iridectomy with good results.

This conjunctival flap method was introduced in this hospital by Lieut.-Col. G. Fowler, I.M.S., Civil Surgeon, Raipur; and I am grateful to him for his permission to publish these short notes.

CAUSES OF BLINDNESS.

A Statistical Report from the Swedish Mission Hospital, Tirupattur, Rannad District, for a period of ten months (from 1st January to 31st October, 1928).

BY G. JOSEPH GNANADIKAM,

Swedish Mission Hospital, Tirupattur, Rannad.

It is the experience of almost every eye surgeon in this country to encounter at least one

patient a day for whom he can do nothing. If a report could be taken from every eye hospital of cases of blindness that attended, it would present a fairly accurate survey of the causes of blindness in India. The following is a table prepared from cases that attended the Swedish Mission Hospital, Tirupattur, Ramnad District, and can be claimed to be a relative index of the various causes of blindness, at least in this part of South India (Ramnad, Tinnevely, Madura, Trichinopoly and Tanjore Districts).

No.	Name of the Disease.	One or both eyes affected.	Blindness.	
			Partial. cys.	Complete. eyes.
1.	Trachoma	.. Single	17	10
		Double	22	5
2.	Gonorrheal ophthalmia	Single	6	2
		Double	12	12
3.	Keratomalacia	.. Single	26	15
		Double	17	14
4.	Keratitis	.. Single	18	..
		Double	5	..
5.	Smallpox	.. Single	23	21
		Double	14	12
6.	Staphyloina	.. Single	8	20
		Double	3	17
7.	Corneal ulcer	.. Single	96	57
		Double	19	10
8.	Corneal scars (after ulcer)	.. Single	60	25
		Double	16	25
9.	Corneal scars (after injury)	.. Single	20	10
		Double	6	2
10.	Injury of eye	.. Single	35	14
11.	Iritis, irido-cyclitis, etc.	.. Single	35	23
		Double	11	16
12.	Glaucoma	.. Single	75	128
		Double	46	93
13.	Inoperable hypermature cataract	.. Single	..	17
		Double	..	2
14.	Couching	.. Single	18	48
		Double	..	5
15.	Failed operation (from other hospitals)	.. Single	2	7
		Double	1	..
16.	Sympathetic ophthalmia	.. Single	3	5
17.	Optic atrophy	.. Single	3	1
		Double	26	24
18.	Retro-bulbar neuritis	.. Single	..	1
		Double	6	3
19.	Retinitis pigmentosa	.. Single
		Double	9	2
20.	Other fundus diseases	.. Single	9	9
21.	Microcornea and other congenital affections	.. Double	33	14
		Double	5	5
22.	Panophthalmitis	.. Single	..	31
		Double	..	4
23.	Phthisis bulbi	.. Single	..	80
		Double	..	31
24.	Tumours	.. Single	..	8
		Double	..	2
Total number of eyes affected			..	2,044
Total number of eyes treated during the period of ten months			..	10,196

Note.—“Partially blind” means sight from detection of hand movements, to moving about with difficulty. Even patients who can read only big characters are not taken in.

Going through the above table, one easily notes the folly of procrastination, so markedly shown by the large number of patients suffering from

glaucoma, over-ripe cataract, and perhaps optic atrophy. In many instances poverty also plays a part. By the time a patient is able to save funds enough for a journey to the eye hospital, the sight is gone. Want of intelligence also may be said to contribute a share: the patient realises that he is blind only very late. Want of facilities for immediate attention is shown by the large number of cases of blindness due to corneal ulcer, injury, iritis, and possibly panophthalmitis. One well knows how much early treatment can do in such cases. The couchers claim a good share in blinding many. It is a pity they should thus go on unchecked. It will be seen so many as 142 eyes are classified under phthisis bulbi. It was impossible to elicit from the patient the precise cause of the condition.

It may not be out of place to quote here the statistics of the blind children in the School for the Blind at Palamcottah. This is taken from the school's latest annual report.

	Boys.	Girls
	per cent.	per cent.
Corneal Affections (scars, staphylo- mas) smallpox 14.9 per cent. other- wise 23.8 per cent.	..	38.7 26.5
Atrophy and phthisis bulbi	..	35.2 49.3
Congenital defects (including con- genital cataract and fundus affect- tions)	..	14.8 18.2
Injury	..	1.1 1.5
Optic atrophy (non-congenital)	..	4.3 1.5
Cataract (non-congenital)	..	4.3 ..
Glaucoma	..	1.1 1.5
Sighted (fairly good vision)	..	0.6 1.5

The conclusion arrived at by the specialist who examined the children is, “The statistics, both for boys and girls, demonstrate the very large amount (practically 75 per cent.) of affections caused by diseases that, under favourable circumstances, might have been preventable.”

The only object of sending this for publication is to show the *overwhelmingly large number of cases of preventable blindness in our country*. As was said before, poverty, procrastination, absence of hospitals nearby, and illiteracy are the main causes. As a remedy, two things could be suggested; first to open more hospitals especially in rural parts, and secondly to start itinerant hospitals in every district not merely for eye treatment, but also for educating as well as warning those suffering from such unwary diseases as glaucoma, etc. In a vast country like India, itinerant hospitals will be of great use, and if once started, will certainly come to stay till every hamlet has a doctor.

If similar reports from other hospitals come in, they will be of much instructive value.

My thanks are due to Dr. F. Kugelberg, M.D., the Chief Medical Officer, Swedish Mission Hospital, Tirupattur, Ramnad District, for kindly helping me in the preparation of this article and permitting me to send it for publication.

A MODIFIED SIPPY'S LINE OF TREATMENT IN DUODENAL ULCER.

By B. G. VAD, M.D.,

and

N. W. KULKARNI, M.B., B.S.,

Sir J. J. Hospital, Bombay.

THE difficulties in the early diagnosis and treatment of cases of duodenal ulcer are well known to the medical profession. Before the introduction of the new lines of treatment by Sippy, Lenhart and others, and of their modifications, surgical interference was supposed to be the only treatment for a radical cure, and even now the same view is held by many surgeons. Having seen a few cases treated by operative methods doing quite well for a few months, but showing signs of recurrences, perhaps in an aggravated form, it was decided to give a trial to a modified Sippy's line of treatment. Suitable opportunities did not come in soon, as the treatment requires the intelligent co-operation of the patient who must be prepared for a period of rigid abstinence.

In this line of treatment, diet is as important as drugs. The patient is allowed to take nothing but a limited quantity of milk at stated intervals for a month or so. Wines, smoking and even tea are strictly forbidden. All septic foci must be attended to. The details of the treatment as given by us are as follows:—

7 a.m. Bismuth oxycarbonas, oz. $\frac{1}{2}$, suspended in 10 ounces of water, to be sipped, and the patient to lie on the right side.

7-50 a.m. Olive oil, oz. $\frac{1}{2}$.

8 a.m. Feed I.

i.e., Sodium citrate grs. 10.

Magnesium oxide grs. 10.

Macilage q.s.

Aqua dr. 2.

added to 7 ounces of milk.

9 a.m. Mixture I.

i.e., Creta preparata grs. 10.

Bismuth oxycarbonas grs. 30.

in as little water as possible.

9-50 a.m. Atropine sulphate gr. $\frac{1}{200}$, by mouth.

10 a.m. Feed I.

11 a.m. Mixture I.

11-50 a.m. Olive oil oz. $\frac{1}{2}$.

12 noon Feed I.

1 p.m. Mixture I.

1-50 p.m. Atropine sulphate gr. $\frac{1}{200}$ mouth.

2 p.m. Feed I.

3 p.m. Mixture I.

3-50 p.m. Olive oil oz. $\frac{1}{2}$.

4 p.m. Feed I.

5 p.m. Mixture I.

5-50 p.m. Atropine sulphate gr. $\frac{1}{200}$ by mouth.

6 p.m. Feed I.

7 p.m. Mixture I.

7-50 p.m. Olive oil oz. $\frac{1}{2}$.

8 p.m. Feed I.

9 p.m. Mixture I.

9-50 p.m. Atropine sulphate, gr. $\frac{1}{200}$ by mouth.

10 p.m. Feed I.

11 p.m. Mixture I.

Close down by an injection of atropine sulphate gr. $\frac{1}{100}$, hypodermically, just before going to bed.

The milk should be gradually increased till the patient takes 10 ounces at each feed in about a fortnight to three weeks' time. In about a month's time, if there be no pain or any other symptom, a little custard or pudding, biscuits, some cocoa or some chocolates may be allowed. Afterwards he should be allowed gradually to take some soft portion of bread and butter, half-boiled eggs, etc. In about five or six weeks' time the patient should be permitted to take some meat and fish, a little minced chicken etc. till he gradually returns to his normal diet. In vegetarians the return to the normal diet is more easily adjusted. In all cases the patient must be warned against indulgence in fried and hot things, chillies etc.

If the patient complains of diarrhoea, the magnesium oxide in each feed should be diminished. If the patient complains of some acidity or pain on rising in the morning, he should be advised to take a feed of milk some time in the small hours of the morning, if he wakes up. After six weeks' treatment on these lines, the patient should be advised to give up the drugs gradually.

As the treatment involves a strict and to some extent tiresome routine, it was possible to try it in only three cases. All these three patients carried out the instructions in every detail and the results obtained have been consistently good. It has been possible to keep in touch with two of these patients, who after the treatment are not only free from any of the symptoms for the last many months, but have steadily gained in weight and are enjoying perfect health. (vide weight graph.)

The accompanying Table I, gives a precis of a few cases of duodenal ulcer that recently came under our observations.

The two important laboratory findings on which stress is laid, viz., the presence of occult blood in stools and marked hyperchlorhydria, may be absent. This is especially the case in patients who come under observation for diagnosis and treatment after having undergone for some time treatment by alkalies and milk diet. The two findings may have significance in cases which seek diagnosis and treatment for the first time. Moreover, in view of the recent findings by various workers, diagnostic significance cannot be attached to the percentage of free hydrochloric acid in the gastric contents. Diagnosis will have to be made chiefly by clinical findings, aided by x-ray examination.

It is not necessary here to enter into discussion of the rationale of this line of treatment, which aims at keeping the site of the ulcer completely free from free hydrochloric acid, which is supposed to retard the healing. The advantage in this line of treatment is that once the ulcer is healed up, the chances of recurrence are very much less than

TABLE I.

Note the drop in weight during the 1st week or two, and the gradual increase in subsequent weeks and months in all the 3 cases after the commencement of the treatment.

only hope for those who will not co-operate.

These observations were carried out in the wards of Lt.-Col. S. S. Vazifdar, M.R.C.P., I.M.S., Senior Physician and Superintendent, Sir J. J. Hospital, Bombay, to whom we are obliged for his kindness and help.

A NOTE ON THE ANOPHELINE FOUND IN BARODA CAMP *

By W. J. WEBSTER, M.C.,

MAJOR, I.M.S.,

A STUDY of the known distribution of the Indian Anophelines(1) appears to indicate that the following record is of interest, as no previous report is quoted from the district in question.

In the course of a calendar year (1927) of general duty in Baroda Camp, a regular watch was kept on the local anopheline population

and the following eight species were encountered.

1. *A. subpictus*. This was quite the commonest anopheline and it took every opportunity of breeding in stagnant pools and in any artificial water container.

2. *A. culicifacies*. A large number of this species was captured in bungalows and outhouses in the latter months of the year. Larvæ were found in pools of rain-water after the Baroda floods. In July 1927 the district was under water for miles in all directions and the potential breeding-places were of much greater extent than usual. It is possible that this species is less numerous in a normal year. It had not been noticed earlier in the year, but may have been overlooked, especially as the resting attitude is said to be that of a culicine.(2) As a matter of fact the great majority of mosquito larvæ found while the floods were subsiding were culicines and *A. rossi*.

3. *A. stephensi*. Adults of this species were captured in bungalows and outhouses occasionally throughout the year. Larvæ were found in wells and tanks, and once in a rain-water pool along with *rossi*, and on another occasion in a pool of clear seepage water in a nullah.

4. *A. fuliginosus*. This species was common, but no breeding-place was found within the camp. In the neighbourhood, however, several tanks and some stretches of water in river beds were found to contain large numbers of *fuliginosus* larvæ. All these breeding-places contained clear water with considerable aquatic vegetation. No other anophelines were found along with these but culicines were constantly present. Breeding continued throughout the hot weather. From examination of a large number of larvæ it was concluded that the internal occipital hair of *fuliginosus* larvæ is nearly always simple, occasionally forked, but never branched. There has been some confusion in the literature over this point.(3)

5. *A. theobaldi*. Anophelines of this species were occasionally captured in bungalows and outhouses, and were bred out from larvæ found in a clear pool of seepage water in a nullah bed.

6. *A. jeyporiensis*. A few adults of this species were captured but the larvæ were not located.

7. *A. funestus (listoni)*. Two adult females were caught in a bungalow. No breeding-place was discovered.

8. *A. maculipalpis*. One adult of this species was bred out from a larva found in a few drops of seepage water, and one was caught in a bungalow.

Hehir (4) gives a list of Indian vectors of malaria in order of importance, and it is of interest that the first four on his list have

* Published with the permission of the Director of Medical Services, India.

been found in the square mile which constitutes Baroda Camp, namely, *culicifacies*, *listoni*, *stephensi* and *fuliginosus*.

PLASMOQUIN IN PREGNANCY.

By K. V. THAKKAR, I.M. & S. (Bom.),

Chief Medical Officer, Idar State, Bombay Presidency.

THE treatment of malaria during pregnancy has always required a special degree of care and caution on the part of the medical man. "Quinine in Pregnancy" was the subject of several letters in the correspondence columns of the *Indian Medical Gazette* in 1909, and I then reported a series of cases of malaria in pregnancy successfully treated with quinine. That large doses of quinine can be taken without any ill-effects in pregnancy is well established. But it is also an equally well established fact that quinine occasionally acts as an embolic, and is actually made use of to intensify the labour pains or to re-establish them during the course of parturition.

The advent of plasmoquine therefore induced me to try this new preparation in malaria in pregnancy. The first case I treated was in September 1927, a primipara in the 5th month. A dose of sodii bromide grs. x. was given each time, prior to the administration of one tablet of plasmoquine thrice a day. On the second day, the patient against instructions took the tablets without the bromide, as she did not quite like the bromide and thought it was a heating thing. No harm came of the omission, and thereafter she was asked to take the plasmoquine tablets alone, without the bromide. The result was quite good, the fever being checked and the pregnancy uninterrupted, after three courses of plasmoquine with the necessary 4 days remission of treatment. During the last year I have treated four more females in different stages of pregnancy with plasmoquine and without any ill-effect on the uterus. The period of pregnancy in these cases was from three to eight months and the malarial attacks were properly controlled in all but one. In the last case, it was difficult to make the patient take the plasmoquine regularly, owing to her unwillingness to take any drug during pregnancy.

The number of cases treated is too small for any conclusions. But it is sufficient to convince one that in plasmoquine we have a drug which is a useful addition to our armamentarium, as a substitute for quinine, of equal if not of superior value, in cases of pregnancy complicated by malaria.

A VACCINE FOR THE TREATMENT OF PHTHISICAL PATIENTS WHO EXPECTORATE TUBERCLE BACILLI IN THE SPUTUM.

By S. MALLANNAH, M.D., D.P.H.,
Hyderabad, Deccan.

THE search for a specific remedy against tuberculosis is as old as the history of medicine itself and hence there exist hosts of drugs recommended for the purpose, but there exists no drug which has a specific action against tuberculosis except tuberculin, discovered and introduced by Koch in the year 1891. Koch advocated tuberculin especially in afebrile and incipient cases, and there is no doubt that in such cases there is no remedy that can surpass it as regards its efficiency. He also warned emphatically against its use in advanced and febrile cases. But unfortunately the drug was abused and it came into disfavour. Besides in advanced cases there is always a secondary and mixed infection, the significance of which was then not fully recognised, and hence tuberculin was found useless in advanced cases. In actual practice tuberculosis of the lungs is diagnosed when it is far advanced and not amenable to tuberculin treatment. Later, the use of very small doses producing no reaction, known as the reactionless method of injection, was advocated by Goetsch in Germany in the year 1901. Wright in England in the year 1903 introduced the use of minute doses of tuberculin after estimating the opsonic index of the blood as a guide to treatment. But later the estimation of the opsonic index was given up as it was found unessential and took up much time in its technique. This method is largely used in localised tuberculosis such as lupus, tubercular ulcers of the skin, tubercular adenitis of the neck, and tuberculosis of the bones, joints, and urogenital system with marked success. But in cases of pulmonary tuberculosis, especially in advanced cases, this treatment is useless, and there is no treatment known which is satisfactory.

During the last few years I have been working at the preparation of a vaccine for the treatment of such cases and I have secured a vaccine which seems to me to possess a remarkable influence in reducing the temperature and the number of germs in the sputum of patients treated with it.

The method of preparing the vaccine is as follows:—

The sputum of the particular patient is collected in a sterile wide mouth glass stoppered bottle and then an equal volume of carbolic acid solution (5 per cent.) with distilled water is added. The whole is well shaken and heated in a water bath at 70°C. for an hour on three consecutive days. It is then treated with an equal volume of chloroform and ether for an hour, while shaking the bottle well all the time. The supernatant fluid after removing chloroform and ether is taken and sterile vaccine bulbs of 1 c.c. capacity filled with it and sealed. These bulbs are heated in a water bath at 70°C. for an hour on three consecutive days.

The emulsion thus treated and purified is a clear opalescent fluid and is free from living germs. When injected into a healthy rabbit it produces no local reaction or rise of temperature and it is harmless.

I have named the vaccine "phthisin" in order to distinguish it from tuberculin, and it differs from tuberculin in the four following points:—

1. It is an auto-vaccine of *tubercle bacilli* derived from the patient.
2. It also includes auto-vaccine of other organisms of the mixed infection which may be present in the patient.
3. *Tubercle bacilli* are here defatted and hence they are easily attacked by the phagocytes and body fluids of the patient.
4. As the vaccine contains inflammatory exudate, there is a probability of the existence of anti-tuberculin in it.

This vaccine when injected subcutaneously into a phthisical patient produces no reaction or rise of temperature, but on the other hand it reduces the existing temperature. This decline of temperature lasts for three or four days and patients feel relieved for the time being. Injections (beginning with $\frac{1}{2}$ c.c. and gradually rising to 1 c.c.) are given once a week.

On repeating the injections the germs in the sputum are not only decreased in number but become thinner and shorter and ultimately become highly granular until they disappear altogether from the sputum. Physical signs in the chest gradually clear up if the case is not far advanced. Meanwhile the patient's strength has to be supported by means of nutritious food in the form of eggs, meat and milk and a tonic (such as Scott's emulsion of cod-liver oil with hypophosphites). I have found administration of fresh normal goat serum 10 c.c. (obtained from the Bengal Immunity Co., Calcutta) intramuscularly now and then helps to keep up the strength. As fresh air is very important, the patient must be kept in the verandah day and night and as exertion of any kind causes rise of temperature, absolute rest should also be enforced. In my private practice I am in the habit of prescribing Musculosin (Byla) and Kinazyme (Carnrick) also.

A SUGGESTION FOR IMPROVEMENT IN THE DIETARY OF THE INDIAN COMMUNITY TO SECURE A HIGHER DEGREE OF HEALTH AND EFFICIENCY.

By A. MALLANNAH, M.D., D.P.H.,
Hyderabad, Deccan.

It is a common observation that Indians are physically weaker than other nations and possess a lowered resistance to infections of all kinds. It is true that infections are caused by germs, and a good deal of useful work is being done in the prevention of disease by medical men, but there is another important factor, i.e., lowered resistance, which is generally neglected in dealing with infections. This lowered resistance found among Indians is due largely to the diet. The vast majority of the population live upon a

purely vegetarian diet which does not contain sufficient and proper proteins, for example rice and Indian corn. The protein found in the latter, known as *zein*, is not suitable for promoting and maintaining growth as it does not break up into amino-acids like tryptophan and lysin which are necessary for reconstruction into the necessary tissues during life. It is also well recognised now that in order to make a vegetarian diet wholesome and efficient, it should be combined with a liberal amount of milk or its products. This is not possible for the majority as they are not able to purchase milk in sufficient quantity to make the diet efficient. Secondly, the milk can never be obtained germ free. Hence it is not safe unless it is pasteurised. Very few have the knowledge and the time at their disposal to do this thoroughly. Besides, cow's milk produces summer diarrhoea and tuberculosis among children if not properly pasteurised. Thirdly, the quantity of milk required to make the diet efficient contains a large amount of water, which puts a strain on the kidneys, and hence it is not advisable to use milk for a lengthened period of time. This is why milk, though considered an ideal diet for infants, is not so for adults. A vegetarian diet, as it contains a large amount of starch in proportion to protein, besides causing bowel troubles, predisposes to diabetes, especially among those who do not take sufficient exercise but have a lot of mental work, and also induces one to obesity when used liberally, and underweight when used sparingly. It is a great mistake to eat more than the body needs and so to grow stout, but it is much worse to eat less than the body needs and so to grow thin.

Unfortunately undernutrition is the chief cause of producing the lowered resistance and physical deficiency found in India. In both conditions the amount of protein assimilated is less than the body needs and hence there is a necessity for the addition of milk and meat to the diet. The protein introduced into the body in the form of meat leaves more residue than the protein derived from plants and this causes angmentation of the viscosity of the blood, resulting in arteriosclerosis. Secondly, meat produces undue putrefaction of protein in the intestines. The absorption of products of putrefaction into the system also causes arterio-sclerosis, the disease which destroys more life than any other disease after the age of 45 and is the chief cause of premature senility. Thirdly, as protein derived from meat contains more purin bodies than vegetable protein, excessive meat diet causes gout and kidney diseases. Lastly, a meat diet, instead of increasing one's endurance, as it has been shown recently, like alcohol, actually reduces it. It is a well recognised fact that the diets of both the well-to-do and the poor are not ideal and scientific, as the former contains too much protein and the latter too little. Both are physiologically unsound and unjustified.

Recently it has been shown that soya bean, being nutritious and palatable, is a wholesome, safe and complete food devoid of infection in itself and not easily liable to contamination. The soya bean, the seed of *Glycine hispida* a leguminous plant, has the appearance of a pea rather than a bean. It grows on a small weak-stemmed plant of the same type as a dwarf garden pea. The plant grows to a height of 7 to 9 inches only and carries 4 or 5 stalks having large, broad trifoliate leaves. The leaves are ovate, having palmate venation, and are 3 inches long and 2 inches broad. It bears tiny white flowers and pods $1\frac{3}{4}$ inches long and $\frac{1}{2}$ inch broad containing 3 or more seeds. The seeds are $\frac{3}{8}$ inch long and $\frac{1}{4}$ inch broad when fresh. It takes more than 2 months to bear seeds. The plant is not a creeper and has no tendrils. It is a heavy cropper; three crops per year can be obtained from the ground. It has the power of obtaining nitrogen from the air and its cultivation enriches the soil. It can be easily, cheaply

when examined under a microscope, and no starch granules as it does not react to iodine. The beans can be taken raw and fresh as they are sweet and agreeable to taste. They may be taken as a vegetable by soaking in water for 12 hours for the skin to come off and then boiling in salt water until they become soft and flavoured. The flour of the seeds is yellow and can be utilised as a gruel in broth or soups and can be made into biscuits and bread resembling gingerbread when mixed with a certain amount of wheat flour. As it contains no starch, soya bean can be used by diabetics freely and advantageously. Commercially, milk can be prepared from it as was done successfully during the Great War at Letchworth, cheaply and economically and without any risk of infection. The flour can be used to prepare scones, cakes, puddings, chocolates and cream. Ice cream can be prepared quickly and cheaply from it. As the curd formed from the milk prepared from these beans is soft, soluble, and assimilable, soya bean

cultivated and procured easily. The plant is indigenous to Manchuria where soya bean forms a staple article of diet from time immemorial. The Manchurian peasantry are well aware of this amazing little plant and make a drink from it in a rough and ready fashion by mashing it up with a pestle and mortar and infusing it with hot water. The resulting liquid resembles milk, not only in appearance, but possesses nutritive properties similar to those of milk when ingested. It is a recognised fact that Manchurians, both adults and infants, thrive well upon it.

The dry seeds are yellow and oval with the hilum flattened, and they possess a thin greyish coloured skin through which the yellow is seen. On account of the yellow color and the fact that it contains

is superior to cow's milk in the dietary of infants, young children, sick and convalescent persons. Cheese can also be prepared from it. Hence the introduction of soya bean into the diet is the best way to insure a high degree of health and efficiency among Indians and has many advantages over meat and milk.

SUMMARY.

As undernutrition is the chief cause of lowered resistance and physical deficiency in India, especially among the poor who cannot afford to buy meat and milk in sufficient quantity, the introduction of soya bean liberally in their diet would be a boon to the community.

Among Hindus especially, vegetarians who do not use meat on account of religion, the introduction of soya bean in place of lentils has great advantages. As lentils are hard to digest, they cannot be taken in sufficient large quantity.

Secondly, the protein found in lentils is not completely assimilable as in milk, so a part of it undergoes putrefaction. Thirdly, lentils contain purin bodies, though less than in meat, and are hence objectionable. Lastly, lentils contain much starch, whereas soya bean contains none, hence soya bean is more suitable than lentils to go with a rice diet which is nearly all starch.

In a hot country like India one needs less food, particularly less meat, and among the well-to-do who take a large amount of meat the introduction of soya bean to replace a part of meat would diminish the ill effects of too much meat and thus help them to lessen the intake of meat. So both vegetarian and meat diets can be improved immensely by the introduction of soya bean, partly by taking the place of the inadequate supply of milk and partly by replacing meat without producing disadvantages of both. The ideal diet is a mixed diet containing milk and its products, fish, eggs, cereals including whole wheat bread, nuts, a liberal amount of green vegetables including soya bean, fruits and a minimum amount of meat.

Lastly, soya bean being rich in potash, lime and vitamins, is well suited for encouraging growth and maintaining the tissues in a state of health. A diet lacking in potash causes baldness and obesity, and a diet lacking in lime causes decay of the teeth. Soya bean, besides being a hard and solid food containing cellulose, requires chewing. This exercises the jaws and thus improves the condition of the tooth sockets and teeth and insures the flow of saliva and gastric juice. This bulky food not only satisfies hunger but helps to regulate the bowels, whereas concentrated food causes constipation. It should be emphasised as it is not generally recognised that even if enough food is ingested, undernutrition may occur if the food is not sufficiently varied. Organs and tissues require for the proper performance of their functions not only protein, starches and fats but also vitamins and certain nutrient salts, for example the thyroid requires iodine, the ovary and blood iron, the heart and teeth lime, the brain phosphorus, the bones lime and phosphorus, the hair sulphur, and the skin silicates. Hence a diet containing deficiency of vitamins and salts, by causing endocrine deficiency, may predispose tissues to the chronic infections so commonly observed among the people of India.

TATTOOING OF THE CORNEA WITH PLATINUM CHLORIDE SOLUTION FOR LEUCOMA.

By B. P. BANAJI, F.R.C.S.I.,
Taj Mahal Hotel, Bombay.

THIS method of colouring a leucoma black came into existence three years ago. Its technique has been described by Dr. G. Krautbauer, one of the assistants of Professor Axenfeld of Freiburg in the *Klinische Monatsblätter für*

Augenheilkunde for March, 1928. Personally, I have found its use very satisfactory. The details of technique are as follows:—

1. Instillation of a cocaine-adrenalin solution, 4 per cent., about three times.
 2. A quick washing out of the conjunctiva with sterile water (not saline) for a quarter of a minute.
 3. Careful scraping of the epithelium over the leucoma with a von Graefe's knife, or a sharp spoon, not going deep. No washing after this.
 4. Application of platinum chloride solution, 2 per cent., with a cotton swab (not dripping) for two minutes over the raw surface. For this purpose a thin wooden probe is wrapped round with cotton at its end, and only the foremost two-thirds is soaked in the solution. Then the point is applied with slight pressure to the raw surface of the leucoma. In this way the leucomatous surface is sufficiently impregnated, while the upper dry part of the cotton by its aspirating action will prevent any excess of the solution from dripping over the cornea.
 5. Next drop from 8 to 10 drops of a 2 per cent. solution of hydracin hydrate over the spot for 20 to 25 seconds. (This solution should not be more than 4 weeks old.)
 6. Immediately wash out the eye with sterile water to remove any excess of solution.
- In about two minutes the reduction of the metal is complete, and the leucomatous area assumes a dark tint.
7. The conjunctival sac is then washed out with normal saline.
 8. Boric ointment is applied and both eyes are bandaged for two days.

BREATH SUCKER SNAKES.

By KIDAR NATH DUTT, L.S.M.F.,

In charge, Canal Dispensary, Chandna, Bahawalpur State, S. P. Railway.

THIS variety of snake is fairly common in the desert Cholisthan area of Bahawalpur State in the summer months from June to September. At first sight no one would believe that the snake has the habits which characterise it, but the writer has seen both the snake and its victims.

The snake does not bite, and has no fangs, but possesses a peculiar enmity to man. During the day time it is blind and harmless and can be easily handled. Often it can be traced to its hole in the ground by a peculiar mark which it leaves on the ground. At night time it will avoid a bright light, and for this reason officers touring this area surround their tents with barbed wire and keep a lamp burning inside all night. Others light fires to protect themselves against the attacks of the snake. It is said that its body is so elastic that it cannot be easily killed with blows of sticks, or *lathis*, and that the best method of destroying it is to throw it into the fire.

The snake is said to have a blister in its mouth, which irritates it, and it is to get rid of this that it attacks man.

At night and in the dark the snake enters human habitations when the inmates are asleep, and it is stated that its first action is to remove any articles with which it could be attacked, such as sticks, *lathis*, or shoes, away from the bedside of the sleeper. It then imperceptibly crawls on to its victim's chest (or, some say, on to his face only). In order to relieve the irritation of the blister in its mouth, it places its mouth over the mouth of the unconscious victim; then either the blister bursts, or the snake ejects some poison into the victim's mouth. Having accomplished its purpose, before leaving its victim, the snake awakens him with a forcible blow of its tail to see the end of his days. The snake has been seen by its victims escaping in the dark.

The venom is very fatal and acts in a very short time, the patient feeling a sweet taste in his mouth, then a choking sensation, then falling into a swoon from which recovery occurs in but very few cases. Some patients cry for help, and if vomiting can be induced they may recover. It is said that if a patient survives till daybreak he will die as soon as the sun rises, and that light is very inimical to the patient. To protect such patients from the light, people dig pits under ground and cover their mouths with bushes; others close all openings of their huts with mud.

Two drugs are commonly used in this locality for the treatment of such patients; (i) the first, the grease from the common Indian tobacco pipe (*hukka ki mal*): (ii) the second, copper sulphate dissolved in water. Both act as emetics. It is believed that if vomiting can be produced very early, the patient may live.

The time to death may depend upon the dose of poison injected. Many such persons who have gone to bed in perfect health and with no ailments whatever, have been found dead the next morning. The cause of death has been attributed to the "sucker snake," which has been definitely traced from the marks which it has left, and has been killed and identified. The writer has seen five such cases in which no trace of any bite or injury could be found on the body; in these cases he was summoned for help, but death had ensued before his arrival as long distances had to be covered to reach the patient's house in each instance.

I beg to request readers of this journal to supply information as to whether they have ever come across such a snake. One specimen of this snake has been preserved in spirit.

[Note.—We have shown the above account to Lieut.-Col. H. W. Acton, I.M.S., who urges us to publish it as typical of the legends and myths which gather around the subject of snake-bite in India. The snake is probably the perfectly harmless *Eryx johni*—John's earth snake, or the "two-headed snake," so-called from the fact that its head and tail resemble one another on a superficial examination. The qualities attributed to this snake all over India are of the most widely

varied and picturesque order. This snake prefers sandy soils and frequently burrows near the roots of trees, where it lies in its burrow awaiting such prey as may come near, e.g., beetles, frogs, and small animals. It often attains a considerable length, e.g., 3 ft. to 3 ft. 6 inches. It is sluggish in its movements and very easily handled during the daytime.

We have asked the author to send us a specimen for identification, if possible. Meantime, we wonder how so detailed and so elaborate a legend can grow up around a harmless snake. We would like to make a present of this "sucker snake" to any novelist in search of really exciting material; its dramatic attack by night could be woven into a story worthy of "my dear Watson."—EDITOR, I. M. G.]

A Mirror of Hospital Practice.

AN INTERESTING CASE OF RECURRENT PREGNANCY TOXÆMIA.

By SUDHIR CHANDRA BOSE, B.Sc., M.B.

Mrs. P. an Anglo-Indian lady, 18 years old, full term, was admitted to the hospital on the 1st of July, 1923. Measurements of the pelvis were found to be normal. The vertex was presenting. Urine examination revealed excess of albumen. She complained of no pains and the head was not fixed though her expected date was the 1st of July. The systolic blood-pressure was 120 mm. of Hg. The patient looked perfectly healthy but complained of occasional headaches and sleeplessness and for this she had hypnotics. On the 5th, the urine was tested again and there was albumen in it. On the morning of the 7th July, i.e., 7 days beyond her time, she started to get pains but not very effective ones. At about midday, on finding the cervix fully dilated after a vaginal examination, the membranes were artificially ruptured but that did not improve the pains. The foetal heart sounds were found quite good. Two hourly doses of grs. x. quinine were then administered orally for three doses. The foetal heart sounds were counted every half hour, but after the last dose of quinine they gradually began to get slow and the mother also showed signs of exhaustion. Forceps were applied. The baby was born in a condition of white asphyxia with the cord once loose round its neck. All methods of resuscitation failed to revive the child and it died soon after. It was 7lb. 2 ozs. and the head was bigger than normal, the measurements of the head being:—

Circumference	14½ inches.
Bi-parietal	3¾ "
Bi-temporal	3½ "
Mento-vertical	6 "
Occipito-frontal	5 "
Suboccipito-bregmatic	4 "
Submento-bregmatic	4 "

The perineum was completely torn and the cervix was very badly lacerated. The puerperium was stormy for about ten days and a

pure growth of *B. coli* was found in the urine on culture. The urine was examined twice during the puerperium and albumen was found on every occasion. The uterus was retroverted, but it was corrected with a ring pessary and the patient was discharged. She was definitely instructed to put herself under the care of a doctor from the third month onwards, if she happened to be pregnant again. These instructions she did not follow, but appeared for examination in 1924, when she was in her seventh month. The child was found lying breech foremost and the urine was loaded with albumen. A suitable diet mainly consisting of milk, vegetables, and vitamine-containing foods was drawn up for her and she was asked to keep to it. An x-ray examination showed that the child was lying with the breech over the internal os with a hydrocephalic head. On admission to the hospital on 17th August, 1924, when she was near term, the urine showed only a trace of albumen. She insisted on having a living child and wanted to have an abdominal section done. A classical Cæsarean section was accordingly performed on the 29th of July, and a baby with a spina bifida, hydrocephalus, and talipes was delivered. The child died 22 days after the delivery. The mother had an uneventful recovery. A urea concentration test was performed before discharge and the kidneys were found functioning normally but a slight trace of albumen was still present in the urine.

In 1925, she again became pregnant. She strictly followed the dietary ordered for her. There was no albumen in the urine. The second stage was helped with forceps in consequence of her having had a previous Cæsarean section. This happened in the Madras Maternity Hospital. The mother and the baby were both healthy at the time of leaving the hospital.

In 1927, she was admitted twice in the hospital—once on the 23rd of January, for threatened abortion, high fever, tonsillitis, and again on the 17th of February, for an inevitable abortion. The uterus was emptied and she was discharged on the 22nd of February. Her urine was not tested this time.

This year (1928) she was admitted to the hospital on the 9th of September, at full term. The head was presenting, not fixed and the foetal heart sounds were quite good. She had her last period from the 15th to the 20th December, 1927. She was first seen in her third month and was asked to follow the diet strictly. The urine was examined and no albumen was found. On being admitted to the hospital her urine was tested again and there was a trace of albumen (nitric acid test being negative). Indican and phosphates were present and the specific gravity varied between 1,005 and 1,002. Acetone, bile, and diacetic acid were absent. On microscopic

examination no casts were present but only epithelial cells, pus cells and bacteria were present. A urea-concentration test was done and the result was as under:—

1st specimen	..	1.2	per cent.
2nd specimen	..	1.9	" "
3rd specimen	..	1.3	" "
Blood urea	0.02	" "

Wassermann reaction was found negative. The blood-pressure was recorded to be 118 mm. of Hg. systolic and 90 mm. of Hg. diastolic.

She insisted on a Cæsarean section and sterilisation at the same time. This time the head was found to be of quite normal size and the foetal heart sounds good. On the 25th of September, a classical Cæsarean section was performed making a linear incision on the body of the uterus parallel to the former one. The previous uterine scar was found to be quite sound and there were no adhesions present, except some slight attachment of the omentum. The tubes were tied by the double loop method with silk. The uterine wound was sutured with silkworm gut and the omentum was placed behind the uterus. The mother made a speedy recovery without any post-partum complications and the baby also went out perfectly healthy.

I have ventured to record this case as all her pregnancies could be followed so accurately and as it is instructive in various ways.

This case is instructive for the following reasons:—

(1) That the castor oil, quinine, and pituitrin technique is not altogether safe, if the baby is post-mature. Post-maturity spells a bigger and harder head due to the increase in circumference of the head by $\frac{1}{2}$ inch, every week after full term and also due to the deposit of calcium salts on the calvarium. This makes moulding difficult.

The dangers of supermoulding are much enhanced if the technique is followed after the membranes have already ruptured. Professor B. P. Watson records the foetal death rate as 6 per cent. from a follow up of 195 cases and Dr. F. J. Browne 4 still births out of 44 cases—one of which was a large child in a primipara.

In this case either the quinine or the post-maturity or the albumen in the urine might have brought about placental infraction, the consequent foetal anoxæmia pre-disposing to the death of the foetus, but as forceps were used after many hours in the second stage and there was a complete rupture of the perineum, it supports the view of Ballantyne and Browne that "post-maturity itself, apart from large dimensions of the foetus does not appear to be a cause of death, but the danger is concentrated in the intra-natal period when the child is passing or rather being dragged through the genital canal of the mother. The child dies at birth or soon

afterwards on account of injuries received therein."

It is very probable that the forceps caused intracranial hæmorrhage in this case.

Perhaps it will not be out of place to mention that quinine alone is supposed to be successful in bringing on labour in 66 per cent. of post-mature cases. Gellhorn records three cases of foetal death following the quinine technique, but as no post-mortem was done on the babies nothing definite can be said.

If the kidneys are diseased the blood is unhealthy and therefore if conception takes place the ovum and the trophoblast are liable to be affected. Birnbaum says that nephritis of the mother either by toxic influence on the vessels, or by disease of the decidua or by failure in the supply of oxygen, or the effect of poisons—all predispose to either death of the foetus and thus expulsion, or in some cases malformations, e.g., hydatidiform mole often occurs in conceptions during albuminuria.

In this case the mesoblast being supplied with blood contaminated by toxins the foetus developed hydrocephalus; in other cases hydramnios, anencephaly or other monstrosities occur.

It is of interest to note that hydrocephalus is often complicated by spina bifidia, just as anencephalus is complicated by diseases of the adrenals.

(2) That the patient suffered in 1923 and 1924, from one of the mild forms of toxæmias of pregnancy where albuminuria was the main and only symptom. Now, however, the kidney efficiency tests show but slight derangement—thus proving that there is no permanent leak or lowering of the threshold for the passage of albumen.

Cruickshank, Hewitt and Couper classify these cases as the "albuminuric" type of toxæmia.

It will be observed that the patient did not develop eclampsia nor did she have any adherence or retention of placenta, in any of the pregnancies. This was possibly due to correct dieting.

(3) That despite all these accidents the patient conceived again.

The history of the other conceptions, especially the second, should warn us to put the patient on diet early, or as Col. Green-Armytage puts it, "at the time of the embedding of the ovum, when the tissues of the endometrium are digested and eroded by the trophoblast and the end products are thrown into the circulation.....the ovum in its growth and maintenance is a parasite not only drawing on the mother's capital but actually injuring her in many ways."

(4) That it also emphasises the general maxim that "Every woman must be examined after delivery as to the condition and position of the uterus before she is

discharged." By following this, one can save a woman from the bitter and lasting symptoms of acquired retroversion, prolapse and inflammation. An insertion of a ring or Hodge pessary after correcting the position of the uterus which can be discarded after 2 or 3 weeks, and a course of tonics can easily accomplish this.

(5) This case also points out the fallacy of the statement "Once a Cæsarean, always a Cæsarean." Nowadays repeated sections are only indicated in those cases where there is a permanent marked degree of pelvic contraction. It is considered only fair that a patient who has a borderline contraction of the pelvis or who has a normal puerperium in the former section should be given a fair trial, to deliver herself naturally by the vaginal route. But the second stage should be carefully watched and assisted either with anaesthesia or forceps. Pituitrin is to be avoided for the reason that it strains the continuity of the former scar.

(6) The question of sterilisation after Cæsarean section is a moot point: our views are that if there is an organic disease or permanent deformity, sterilisation ought to be done after the birth of the second living baby. If sterilisation is deferred, the dangers of subsequent delivery should be explained to the patient and her husband.

(7) That silkworm gut is the best suture material to be used in Cæsarean section cases according to Eardly Holland, as the former Cæsarean scar was found perfectly sound though an incision of about 7 inches had been made in the uterus in order to deliver the hydrocephalic child.

That where repeated sections are to be performed the classical Cæsarean is the most suitable.

(8) That the urea-concentration test gives very valuable information as to the question of the future diet and welfare of the patient.

My thanks are due to Lt.-Col. V. B. Green-Armytage, M.D., F.R.C.P., I.M.S., our present chief in the Eden Hospital, for kindly permitting me to publish the record of this case, and to Dr. M. Sarkar, Registrar, Eden Hospital for kindly giving me the necessary suggestions.

AN UNUSUAL COMPLICATION OF KALA-AZAR.

By NISANATH GHOSH, M.B.,

Teacher, Medical School, Dibrugarh, Assam.

IN 1926, the writer of this note came across a kala-azar patient with a rare complication—gangrene of the scrotum.

The patient, a Muhammadan male aged about 24 years, was undergoing urea-stibamine treatment for kala-azar. He was a bit negligent about his personal cleanliness. One day while scaling over a low bamboo fencing he had a trifling scratch on his scrotum. In a few days ulceration and gangrene rapidly followed in spite of the usual treatment, and when one side of the scrotal sac was lost leaving one testis exposed, the destructive process ceased and eventually the patient recovered both from the complication as well as from the original trouble.

Years ago, Sir Leonard Rogers observed that about 17 per cent. of kala-azar cases get cancrum oris and that sloughing of the scrotum had also been noticed. Dr. U. N. Brahmachari mentions gangrene of the vulva. Recent research workers like Dr. Napier are of opinion that nowadays, with a better sense of personal hygiene and under more enlightened conditions, the percentage of cancrum oris has dropped down to 2 per cent. only. In this particular case just mentioned, the dirty habits of the patient and the trifling scratch perhaps gave a start to the gangrenous process at an unusual spot.

A CASE OF IVORY-GRAFTING

By S. C. DAS GUPTA, L.M.S.,

Senior Surgeon, Bir-Hospital, Nepal.

A HINDU boy aged 6, was admitted in August, 1926, having a compound comminuted fracture of the left femur, which for want of proper treatment became septic. Under chloroform I enlarged the opening and also

made a counter-opening at the most dependent part, as the cavity was full of pus having no means of outlet, and then kept the wound continuously irrigated by Carrel's method for a few days, but to no purpose. The boy was running a high temperature daily and also having a profuse discharge of pus from the wound; so after a week I again had the patient under chloroform and removed all the loose fragments of the bone and at the same time the upper and the lower ends of the fragments were sawn off by means of a motor saw—the soft parts having been carefully protected from injury. There was a

gap of nearly 5 inches between the ends of the bone. The cavity was then scraped out, irrigated, dressed and put between two side-splints. In six weeks the wound was completely healed up and the general condition of the patient also greatly improved, but the limb was a mere flail and consequently useless.

Then I had a round piece of ivory made; 6 inches in length and about $\frac{1}{4}$ inch larger in diameter in comparison with the removed pieces of bone. I kept it immersed in absolute alcohol for twenty-four hours. Next, I made a longitudinal incision about 7 inches long at the outer part of the thigh and deepened the wound up to the level of the bone and exposed both the ends of the femur. I scraped out the medullary cavity for $\frac{1}{2}$ inch on each side and fitted the ivory piece after traction made on the part from the opposite sides—the narrowed ends entering into the medullary cavities. The lower end fitted

all right, but the upper end was a little loose. So I had the junction of the ivory piece and the bone surrounded by a narrow silver plate and screwed into it. Then the muscles and fascia were sewn together over the graft fairly tight, and the skin was sutured with interrupted silkworm-gut stitches, and the limb was then fixed up in splints. On the 10th day the stitches were removed and after a week the limb was put up in plaster of Paris, which was kept on for two months. On removal of the plaster the graft was found slightly movable, so I applied plaster of Paris again. I removed the same after three months—when the graft was found immovable, and on finding the knee joint stiff I had the limb massaged daily. At this time the boy could stand on both legs with slight support, but could not bear the whole weight of the body on the affected leg only. A month later he could stand well and even walk a few steps with the aid of a stick. After 9 months the boy could go up and down the stairs by holding the bar of the staircase.

I enclose a photograph showing the condition of the patient on 1st March, 1927. The boy came to me several times and I saw him last about a week ago; he can now walk easily half a mile unaided and swim also. The shortening of the operated on leg is only three-quarters of an inch since the operation, i.e., in the course of nearly two years.

My thanks are due to Captain Kaisar Jung Thapa, Radiologist and to Dr. Sidhi Mani Acharya, M.B., for their valuable assistance.

NOTES ON A CASE OF *BACILLUS COLI* SEPTICÆMIA.

By A. BAYLEY DE CASTRO,

LIEUT., I.M.D.,

Military Family Hospital, Quetta.

THESE notes are published because of the rarity of such cases in non-debilitated subjects, and also because of the long and protracted course that the disease may take.

the 22nd September, 1928 complaining of headache, anorexia, and lethargy, which had started on the 6th September, 1928. She never took her temperature at home but thought she got a slight pyrexia at some time daily. She presented a dull expression, and had a dry, brown, coated tongue, with the tip bright red and strawberry-like. She had been reinoculated against enteric fever on the 4th August, 1928. The liver and spleen were not palpable, and no adventitious sounds were heard in the heart or lungs. Slight tenderness and pain on deep palpation were present over the right renal region, and slight pain on micturition. No backache. At the time of admission she was menstruating very profusely but stated that that was her normal period.

She had lived in India for a total of 3 years, and arrived in Quetta from Nasirabad in February 1928. She had her last confinement at Nasirabad in November 1927, the labour was difficult and prolonged, and there was profuse post-partum hæmorrhage. In December, a few days after discharge from hospital, she developed mild scarlet fever.

She gave a negative history to any kidney or bowel trouble, which is interesting from an ætiological standpoint. Her dentures were defective and gums unhealthy, and four stumps were extracted on the 12th October, 1928.

Before admission to hospital she had repeated attacks of urticaria, and during the period of her admission had several attacks also. Blood smears examined for malaria parasites were negative. The blood for Widal reaction showed standard agglutination value: (T. 7, A. 13, B. 9). The faeces showed no pathogenic organisms, but the urine showed a heavy *B. coli* infection. The report from the laboratory stated that "a lactose-fermenting coliform organism was isolated from the urine, and this organism is agglutinated by the patient's serum in a dilution of 1:3,000" (See notes on temperature chart). The blood was sterile on culture.

In the early stages of patient's stay in hospital, rigors, and profuse diaphoresis were marked features of the disease, and these attacks were specially severe on the 22nd, 23rd, and 30th September and the 4th and 5th of October. Most of the rigors and sweats occurred at night, but this was by no means the rigid rule. The treatment from the date of the first laboratory report was a mixture of 1-drachm doses of hexamine and acid sodium phosphate in an ounce of water t.d.s., prior to which intramuscular injections of quinine in doses of xv grs. had been given.

On the 5th October, 1928, 30 c.c. of freshly prepared eusol solution was given intravenously, with gratifying results: (see chart).

On the 8th October, 1928, another dose of these injections was to have been given but her veins were found collapsed, owing to very profuse diaphoresis.

On the 9th October for the first time since admission the headache had disappeared.

Mrs. B., wife of a sergeant of the 1st Royal Welch Fusiliers, aged 32, and the mother of two children, was admitted into the Military Family Hospital, Quetta, on

On the evening of the 16th October the temperature shot up again and on the 17th a 40 c.c. intravenous injection of eusol was given. A pyelitis was suspected

but no pus was found in the urine, and unfortunately no culture was made from the gum pockets after the extraction of the stumps.

The laboratory report on the 20th October, 1928, stated that the urine was sterile, although this was about the middle of the period of her second relapse, which is difficult to account for; but finally on the 26th October she was given 2 c.c. of a 40 per cent. solution of urotropine with very striking results, and from now onwards rapid convalescence ensued and on the 1st November the patient was discharged from hospital.

Discussion. The salient features in the case are:—

(a) *Source of infection.* Was a mild pyelitis present and was that responsible? It is said that these organisms filter through the gut into the kidneys. Be it remembered however that this patient gave a negative history to any bowel complaint. Was the condition of the gums the source?

(b) *Course of the disease and laboratory findings.* In conjunction these two factors are of interest, though it is difficult to account for the relapse. Thus on the 3rd October, 1928, the laboratory reported the finding of lactose-fermenting coliform organisms from the urine which agglutinated by the patient's serum in a dilution of 1:3,000; and on the 19th October, 1928 this dilution figure was reduced to 1:1,000 (*see chart*). Finally the urine was found to be sterile on the 20th October, 1928.

(c) *The long course of the disease.*

AN INTERESTING EARLY RIGHT-SIDED GOITRE.

(With a mild paratyphosis A complication.)

By Lieut. A. BAYLEY DE CASTRO, I.M.D.,

Military Family Hospital, Quetta.

THIS case presented certain features of interest, both in the patient and the train of symptoms she developed.

Mrs. S., a well developed, and healthy looking woman, first came under my observation in June 1928, when she attended the out-patient department of the Military Family Hospital for the treatment of her goitre.

In January 1928 she had received protective inoculation against enteric fever in London. In March she arrived in India, her first station being Jubbulpore, and finally she arrived in Quetta in June of the same year.

Her chief complaint then was palpitation and insomnia. Breathlessness was not complained of. An acceleration of the pulse was often noticed. The area of cardiac dullness was not increased, and the blood pressure was normal.

The goitre was at first the size of half a cricket ball and had developed from the right lobe of the thyroid. But a week after her third injection of sodium iodide it had diminished to some extent. Unfortunately at this period she developed a neurotic tendency, and I

fear—influenced by her husband—started discrediting the treatment.

Nervous System.—The right pupil was more dilated than the left, and the voice was turning hoarse, which factors indicated pressure on the right cervical sympathetic and recurrent laryngeal nerves. All reflexes were brisk, but not pathological. The plantar reflex was flexor. Optic discs normal.

In connection with the goitre, the past history of the patient is of some interest to adherents of the intestinal toxæmic theory. During her girlhood and especially between the ages of 5 and 9 years she suffered from a "weak stomach" and during all this time attended the Great Ormond Street Hospital. The symptoms of this "weak stomach" as described by her, were pain and vomiting, she does not remember any diarrhoea. Even now when it gets cold or damp she suffers from abdominal colic. She married at the age of 20, and a year later the goitre became very noticeable. Her father died at the age of 52 from a heart affection following rheumatic fever. There is insanity in the family on the father's side. Apart from this the family history is negative. According to the patient's statement she felt ill on the 4th August 1928 for the first time since coming to India, and on the 7th, after running a temperature at home for 3 days was admitted to hospital. Five c.c. of blood for culture sent to the laboratory was reported on the 11th to show *B. paratyphosis A*, which according to Manson is the most common enteric infection in India.

The pyrexial period of the disease was remarkably mild. On the 14th August, however, the patient suddenly developed a pain in the right wrist and forearm, and next day there was a distinct swelling on the palmar aspect of the wrist, while careful palpation made evident a teno-synovitis with a myositis of the muscles. The next day the left elbow was painful, but not to the same degree as the right wrist, which for two nights caused disturbed rest. The pain in the left elbow disappeared completely in 48 hours, but that in the right wrist not till the 22nd August 1928.

The urine, examined on several occasions, was never found to be excessively acid.

The patient was discharged on the 15th September 1928, but shortly after began to suffer from headaches and backaches. She was unable to perform her household duties, and suffered from a weakness of the right arm. The grip of the right hand was weaker than that of the left, and a weakness of the lower extremities had also developed. She was finally invalided and left for the United Kingdom on 21st November 1928, and so I lost touch with her.

APYREXIAL PNEUMONIA.

By U. A. KRISHNA IYER.

L. F. Dispensary, Jammalamadugu.

APYREXIAL pneumonia is not an uncommon occurrence in general practice. Some of the sudden deaths after two days' slight fever might be the result of such a condition. Unless every such case is subjected to a post-mortem examination, the rate of actual death from the pneumonia cannot be correctly estimated.

Case No. 1.—A middle-aged man of about 35, previously hale and healthy, was seized at about 3 a.m. one morning with a slight pain in the chest. By 6 a.m. the pain became severe and he was just preparing to start for the out-patient clinic when he got an attack of sudden pain and had to lie down. There followed some convulsive movements of the body with eye-balls

rolling, struggling of arms and legs, foaming at the mouth, and in a few minutes, he was dead. On post-mortem examination there were typical signs of pneumonia of one lung, the beginning of grey hepatization. His condition before post-mortem examination never gave even the slightest clue that he was suffering from pneumonia. The temperature soon after (10 minutes after) death was 100°F. But for the post-mortem examination, his death would have been classified under some fit of cerebral origin.

Case No. 2.—Patient aged about 30 had attended the out-patient clinic the previous day for slight fever and headache. He was given the routine mixture for fever (diaphoretic) and sent away. He worked that day. Just before meal-time, at about noon, he was going to take his food, but on the way fell down fainting and, before anything could be done, expired. But for the post-mortem examination which revealed definite signs of pneumonia just like the first case, he too would have been considered to have died of heart-failure due to, say, "flu."

AN INTERESTING CASE OF "CHOREA."

By S. B. IMAM,

Medical Officer, Khutowna Dispensary (Darbhanga).

A BRAHMIN girl, aged about 9 years, was brought to me from a village in the vicinity of the Nepal border for the treatment of constant sucking movements of the lips, protrusion of the tongue at frequent intervals, and certain awkward movements of the limbs.

Having thoroughly watched the symptoms I concluded that they quite tallied with the book symptoms of chorea.

The intense anæmia, the frequent abdominal pain and the lowered general health of the girl suggested to me that she must be suffering from some worm infection too. On enquiry from the father of the girl I was told that the girl had passed a big "Chali" (round-worm) some two months ago.

I first determined to get the girl freed from the worm infection, and then later on to give her salicylates, arsenic and bromides for chorea.

With this idea she was provided with an ordinary worm powder containing half a grain of santonine.

Four days after I was informed by her father that she had passed some fifty worms in the stool, and that all the other symptoms, viz., sucking movement of the lips, protrusion of the tongue and awkward movements, had ceased.

Having been struck with this information I requested him to bring the girl to the dispensary. The girl was brought to me a week after and to my surprise I found her quite well.

The idea of my writing this article is to show that simply half a grain of santonine could check all the choreic symptoms and

hence I conclude that *Ascaris* infection can also be one of the exciting causes of chorea.

A CASE OF INGUINAL HERNIA WITH A FÆCAL TUMOUR IN THE SCROTUM.

By D. N. GHOSE, M.B., B.S.,

AND

A. K. MITTER, M.B., B.S.

118, Lukergunj, Allahabad.

M., an old man aged about 60 years was admitted to the Colvin Hospital, Allahabad, on the 22 November, 1928, with the complaint of slight abdominal discomfort, nausea, loss of appetite and chronic constipation. He said he had been suffering from this condition for the last 3 months and that his constipation was gradually getting worse every day. He had tried all sorts of purgatives but without any avail.

Though old, he was not constitutionally weak and had kept very good health till the onset of this trouble. On physical examination his tongue was found thickly coated, abdomen slightly tumid but soft. No gland or growth could be detected within the abdomen. Liver and spleen were normal, heart sounds were rather feeble and pulse of low-tension. The only thing found on examination was that he had double-sided inguinal herniæ; on the right side it was only a bubonocoele, whereas on the left side it was a scrotal hernia complicated with a fairly big tumour situated about the middle of the cord. The tumour, he said, was only three months old and had gradually grown to the present size. The tumour appeared neither connected with the testis nor with the contents of the hernial sac, which, however, could easily be reduced with a gurgle, indicating the presence of loops of intestine. The tumour was as hard as a stone and was about the size of a cricket ball, freely movable and seemed not adherent to any structure. The testis on that side was little, atrophied, and had lost its testicular sensation. The cord was normal and was quite separate from the tumour. As the patient was an old man and as he remarked that with the growth of the tumour his constipation became more and more acute, we were naturally led to think that it was some kind of malignant growth pressing upon the loops of intestines in the sac, causing obstruction to the onward passage of fæcal substance. At the same time we were at a loss to understand how it could cause obstruction when the intestines could apparently be reduced.

At this stage, that is on the third day after the patient's admission in the hospital, his

condition became very serious, so much so that he developed hiccough, began to vomit, and showed signs of acute abdomen in spite of high rectal enemata and fractional doses of calomel which he had had from the very day of his admission. The condition of his heart became so very unsatisfactory that operation, which was at one time supposed to be the only way of relieving his symptoms, could not be undertaken without the risk of sacrificing the patient's life, besides, the patient himself did not submit to operation and preferred the palliative treatment.

On the fifth day of the patient's hospital life, the mass, to our great astonishment, was found double instead of being single and its consistency was undoubtedly much softer than before, so much so that it began to pit on pressure. Next day the patient passed a few scybala with the soap water enema and his condition improved a little. The diagnosis was now clear, the tumour which had been mistaken for a neoplasm was nothing but a faecal concretion, lodged in one of the loops of the intestine, although their apparent reduction gave us the false impression of the tumour being not connected with them. Now the patient progressed with the passage of a more and more scybalous stool every time, with the ultimate result that his constipation turned into diarrhoea. The mass had now entirely gone and all his symptoms subsided. The patient was discharged cured and was advised to put on a truss for the rest of his life as he did not like to undergo any operation.

Our best thanks are due to our chief, Dr. B. K. Mukerji, Medical Officer in-charge of the Colvin Hospital, Allahabad, for allowing us to publish this case and for helping us throughout its investigation.

A CASE OF EXFOLIATIVE DERMATITIS AFTER NEOSALVARSAN INJECTIONS.

By INDULAL S. DAVE, M.B., B.S.

Medical Officer, Jannabai Dispensary and Maternity Home, Baroda City.

A SADHU woman aged about 25 years attended my outpatient clinic in January 1928. She gave a history of a succession of eleven miscarriages without any conception having gone to term. On inquiry, she gave a history of her husband having suffered from syphilis before marriage. She was, therefore, advised anti-syphilitic treatment with neosalvarsan injections, both for her husband and for herself. But at first they refused. Then on the 3rd March, 1928, the husband came first to take the treatment. The wife also followed the next day. The following doses were injected intravenously into the patient on dates noted against each.

9-3-1928	0.3 grm.
15-3-1928	0.3 grm.
22-3-1928	0.3 grm.
9-4-1928	0.45 grm.
Total:		1.35 grms.

Thereafter the woman refused any more injections, as she thought she was carrying, because she had missed one period.

On 22-5-1928, i.e., exactly six weeks after the last injection, she was brought to my clinic with the cuticle peeling off the skin at many places, in large areas of both upper and lower extremities and of the abdomen. At some of the places deep extensive ulcers also had formed by secondary infection due to scratching.

The history given by her husband was that about a fortnight after her last injection she got a macular rash which gradually spread all over the body. First, they mistook it for urticaria but when it persisted they took it to be measles. They did not take any treatment according to their religious belief. But when, after a fortnight of the rash, they saw the cuticle peeling off the skin and ulcers forming underneath, they gave her indigenous treatment. The patient was run down due to lack of nourishment and discharge of pus from an extensive raw surface. Ulcers formed in the mouth and the gums became spongy and pyorrhoea alveolaris set up.

In such a debilitated condition the patient was admitted into my wards.

As nearly a month had passed since the rash appeared first, and as urine examination did not give any indication of kidney trouble, I did not deem it desirable to give specific injections of sodii thiosulphate. I simply put her on to the following:—

R	Tinct. Card. Co.	5i.
	Tinct. Cinchona Co.	5i.
	Tinct. Nux Vomica	m.xv.
	Mist. Saline (J. J. Hospital formula)	ad 5iii.
	Fiat mist,	5i. t.d.s.	

The ulcers were thoroughly washed antiseptically and dressed with an ointment of oxide of zinc. The mouth was attended to. She had to be fed with the spoon. During her stay in the hospital she went on improving daily and on 29-5-28, i.e., exactly on the 8th day after admission, she was discharged cured, though with a disfigurement of the body due to extensive white scars.

I have given about 400 injections of neosalvarsan intravenously to patients of several grades in society and of ages from 1 year to 50 years, but never have I seen a similar case of arsenical poisoning. The case very much resembles the one reported in the July 1928 number of the *Indian Medical Gazette* by Sanocrysin injection, with the difference that my patient survived and was cured fully without any intensive treatment.

A CASE OF A RUBBER CATHETER INSIDE THE BLADDER.

By A. K. DUTT GUPTA, M.B., D.T.M.

Assistant Surgeon, Medical College Hospital, Calcutta.

CASES of broken rubber catheters in the bladder are not rare, but the story of a whole catheter being "sucked into" the bladder before the wondering eyes of a doctor during the process of evacuation is perhaps an exceptional one.

The history is that a patient aged 40 years had retention of urine after a short attack of

The patient was admitted into the hospital 4 days after the accident. The end of the catheter could then be felt in the perineum behind the scrotum.

With a direct vision urethroscope the end was seen about 5 inches from the meatus, and with a pair of crocodile forceps the catheter was pulled out.

The catheter was a fairly new one, No. 9 size, and about 16½ inches long. The patient had no stricture in the urethra, which was of normal length. The skiagram showed that

fever and a rubber catheter was passed by the local doctor to relieve the bladder. About an inch and a half of the catheter was outside the external urethral meatus. Towards the end, the doctor was making suprapubic pressure to expel last portions of urine, and, on relieving the pressure, to his utter amazement the catheter seemed to have been "sucked into" the bladder. An attempt at removing it proved fruitless.

the forepart of the catheter was coiled one and half times inside the bladder. It seems probable that a few inches of the catheter was inside the bladder and had been coiled by the suprapubic pressure. On cessation of pressure, the catheter uncoiled partially and then by its elasticity drew in the other end.

My grateful thanks are due to Lt.-Col. Harnett, I.M.S., under whose care the patient was, for permission to publish these notes.

Indian Medical Gazette.

APRIL.

NOTIFICATION OF DANGEROUS DISEASES.

We have received from the Honorary Secretary of the All-India Medical Association a copy of a "Bill for the Prevention of Dangerous Diseases," which Dr. Kumud Sankar Ray, M.A., B.Sc., M.B., Ch.B. (Edin.), has introduced in the Legislative Council, Bengal, and which has been referred to a Select Committee.

The text of the bill is as follows:

PREVENTION OF DANGEROUS DISEASES ACT, 1928.

INTRODUCED BY

Dr. KUMUD SANKAR RAY, M.A., B.Sc., M.B., Ch.B.,
(Edinburgh),

Member, Legislative Council, Bengal.

BENGAL ACT NO. OF 192 .

PREVENTION OF DANGEROUS DISEASES ACT 192 .

Whereas it is expedient to provide for the control and prevention of dangerous diseases in Bengal, it is hereby enacted as follows:—

1. (i) This Act may be called the "Prevention of Dangerous Diseases Act."

(ii) It extends to the whole of Bengal (except places where the Calcutta Municipal Act, 1923 is in force).

(iii) It shall come into force on

2. For the purposes of this Act, unless there is anything repugnant in the subject or context,

(a) Dangerous diseases mean

(i) Cholera; Plague; Smallpox; Cerebrospinal Meningitis; Diphtheria; Open Tuberculosis; and

(ii) Any other epidemic, endemic or infectious disease which the Local Government may, by notification in the *Calcutta Gazette*, declare to be a dangerous disease for the purposes of this Act.

3. Every medical practitioner who, in the course of his practice, becomes cognizant of the existence of any dangerous disease in any private or public dwelling-house, other than a public hospital, shall give information of the same with the least practicable delay to the President of the Union, Panchayet or Chairman of the Municipality or the Health Officer, within whose jurisdiction the disease happens to occur in such form and with such details as the Local Government may direct from time to time.

4. The President of the Union, Panchayet or the Chairman of the Municipality or the Health Officer or any officer employed and authorised by the aforesaid in their behalf may at any time by day or by night without notice or by giving such notice of his intention as may in the circumstances appear to him to be reasonable, inspect any place within his jurisdiction in which any dangerous disease is reported or suspected to exist and take such measures as he may think fit to prevent the spread of the said disease beyond such place.

5. (i) If it appears to the President of the Union, Panchayet or the Chairman of the Municipality or the Health Officer that the water in any well, tank, or other place within his jurisdiction, is likely, if used for the purposes of drinking or for any other domestic pur-

pose, to endanger or cause the spread of any dangerous disease, he may, by public notice, prohibit the removal or use of the said water for such purpose.

(ii) No person shall remove or use for such purpose any water in respect of which any such public notice has been issued.

6. If the President of the Union Board, or the Chairman of the Municipality or the Health Officer or any officer authorised by the aforesaid on their behalf, is of opinion that the cleansing or disinfecting of any building or any part of a building or any article therein which is likely to retain infection, or any tank, pool, or well adjacent to a building, would tend to prevent or check the spread of any dangerous disease, he may cleanse, disinfect such building, part, article, tank, pool, or well and may by written notice require the occupier of such building or any part thereof to vacate the same for such time as may be prescribed in such notice.

(ii) The cost of cleansing or disinfecting any building or part thereof or any article therein under sub-section (i) shall be paid by the occupier of such building and the cost of cleansing or disinfecting any tank, pool or well, under the said sub-section shall be paid by the person in actual possession of such tank, pool or well, or if there be no such person by the owner thereof.

Provided that if, in the opinion of the President of the Union, Panchayet or the Chairman of the Municipality or the Health Officer, the owner or occupier is from poverty unable to pay the said cost, the President of the Union, Panchayet, or the Chairman of the Municipality, or the Health Officer may direct payment thereof from the funds at their disposal.

7. The President of any Union Board, or the Chairman of any Municipality, or the Health Officer may give a reward of any sum not exceeding one rupee to any person giving information about the existence of any dangerous disease at any place within his jurisdiction.

8. It shall be competent for the Local Government to prescribe from time to time what diseases are to be deemed dangerous diseases for purposes of this Act and to publish the same in the *Calcutta Gazette* and to prescribe the form and details to be supplied by medical practitioners under section 3 of the Act.

9. Whoever knowingly contravenes the provision of this Act shall be liable to pay a fine not exceeding Rs. 25.

Statement of Objects and Reasons.

The incidence of infectious and epidemic diseases in Bengal is very high. Every year a large number of people fall victims to the ravages of these diseases, which, under proper control, have been greatly reduced in other countries. The control and prevention of such diseases in this province are an immediate necessity. Prompt supply of information about the existence of any such disease to the authorities in charge of sanitation concerned, particularly from medical men who are conversant with the causes and effect of diseases, should be ensured; and the said authorities should have more powers of control for enforcing notification; so that necessary preventive measures may be taken with the least possible delay. It is with these objects in view that the Bill has been introduced.

Dr. Ray's bill embodies at least one very sound fundamental sanitary doctrine . . it proposes to lay the foundation of securing, or attempting to secure, some real information about the incidence of infectious disease in the municipal and rural districts of Bengal.

Public Health in England had its beginnings in the years immediately following the Great Plague. At the very name "plague" the whole of London was terror-stricken; the Court, the Government and everybody who could fled from London, until the sane persons

asked "What, after all, is this Plague, what damage is it really doing, and what does the actual danger to which we are submitted amount to?" Captain John Graunt stepped into the breach and attempted to answer the question in his interesting and unique studies of the "London Bills of Mortality." In these he showed that the ravages of plague were not so bad as people thought and that a careful study of actual happenings, though it might not deprive the disease of its terrors, at least showed the problem in its proper perspective, and pointed the way to remedy and prevention. From that time the collection of accurate information concerning infectious disease has been one of the main planks in the English sanitary platform. Dr. William Farr showed to all the world to what great uses correct statistical information could be put; common sense and critical reasoning applied to accurate information led to a correct appreciation of the situation; the distribution of disease, its nature and extent, and the probability of its course could be appreciated, remedies devised and put into practice. Dr. William Farr's and Sir John Simon's reports did more than anything else to make public health in England a subject of national interest, and they had one basis, namely, correct information.

In India, the lack of this is one of our greatest disabilities. We have, it is true, some idea of extent of the main diseases like cholera and smallpox, but the real incidence of malaria, enteric fever, tuberculosis, leprosy, dysentery, and diseases like diphtheria, measles, whooping cough, etc., is really comparatively unknown. The sanitary law is vague and shadowy, and still feeling its way. In Bengal, for instance, outside Calcutta, there is no compulsory notification of any disease by anyone. The police are required to give information of any cases of cholera to the medical authorities, and special measures may be put into force for plague—a disease from which Bengal is particularly free. The village chowkidars on Rs. 12 a month as a matter of fact give valuable information of all sorts to the village Unions and District Boards, but in rural municipalities information about everything sanitary is sadly lacking. The notification of common occurrences, such as births and deaths, which is compulsory under law, is from 20 to 50 per cent. in deficiency. What hope then is there of any information about diphtheria, tuberculosis, enteric fever, or even smallpox and cholera being obtained! The Calcutta Municipal Act of 1923, however, marked a distinct advance. In this, certain dangerous diseases (cholera, plague, smallpox, cerebrospinal fever, and diphtheria) are made notifiable by registered practitioners, and the health officer may take such action as he thinks necessary for isolation and disinfection. The real value of this

information and the value of the measures taken, or possible, as the result of the knowledge is still a matter of conjecture. What the sanitarian hopes for is an increase in the number of those who will have eyes to see and ears to hear; it is his aim to have the picture that he wishes them to see and appreciate always true and never false, so that when the scales fall, the public and their responsible advisors will see actual happenings, and through these the real causes and possible salvation.

There are one or two features in the Bill which appear to call for criticism. For example, take section 4. Will the ordinary Bengali householder permit the health authorities—not necessarily the Health Officer, but anybody appointed by the President of the District Board—to inspect his house "at any time of the day or night without notice"? Again section 7 seems to us open to abuse, "any person" anxious to earn a rupee might resort to it. These are in any case only minor objections to the Bill, and may not even be real ones.

Although we are in entire sympathy with Dr. Ray's aims we cannot help feeling that such a Bill—even if passed into law—may be difficult, or even impossible, to work, and may remain on the statute book as a dead measure. Sanitary legislation cannot go ahead, or at any rate far ahead, of public opinion. In India the sanitary conscience is not yet developed to any high degree; there is the dead-weight of centuries of inertia and the stifling influence of certain caste and racial customs to be overcome. The remedy for this state of affairs is not merely legislation from above—you cannot make the village rayat of India sanitary by force of law—but education from below. That remedy has not been neglected, but only the merest surface of the problem has as yet been scratched. Health weeks, baby and health welfare clinics, the model demonstration trains on the Indian railways with their instructional cinema films and health posters—these and similar measures may help to arouse a sanitary conscience in this land. There are the laws of Manu. May it not be possible by incessant teaching and propaganda to supplement them by the laws of personal cleanliness and the observation of the rudiments of hygiene? We would like to see elementary instruction in hygiene—made as attractive as possible by coloured posters, cinema films if possible, and well got up pamphlets—a part of the course of instruction in every elementary and secondary school in India. Indeed, we are far from certain that such instruction is not also wanted for university students in India. It has been well said that Medicine is a legacy of priestcraft, witchcraft, and leechcraft; but present day Preventive Medicine has long ago thrown off those shackles. To-day it is inspired

by the ideal of a public and communal sanitary conscience; and there are not a few factors in the ancient Brahminical and Moslem religions of India which might be utilised in promoting the growth of such a conscience.

Nevertheless we welcome Dr. Ray's Bill. In the Legislative Council a discussion on it alone would justify its introduction, whilst its passage into law would, one hopes, make more possible the collection of accurate data relating to infectious diseases in the Province, encourage a more correct appreciation of the problems that exist, and, possibly, indicate some of the measures necessary to combat them.

It must not, however, be imagined that the passing of such an Act will *per se* achieve anything, nor must legislators allow its passage to lull their consciences. It can only achieve any good result if it is associated with an extensive scheme of steady public health propaganda. Many avenues of contact with the people remain to be explored; there is to-day far too large a gap between the results of medical research in this country and their practical application in the Indian field. Indeed this appears to us to be the immediate problem of the future. We know how to prevent most of the common diseases of India; how can we make that knowledge common property to the citizens of this land?

We fear that superimposed legislation alone is no solution to this problem.

CHEMOTHERAPY.

CHEMOTHERAPY is a word that has come very prominently into use in medical literature during the last two decades. The medical dictionaries say that the word means "the use of chemical substances in therapeutics." Magnesium sulphate is a chemical substance, but chemotherapy would be a somewhat grandiose word to apply to the humble act of taking one's morning dose of salts. The word has acquired a much more specific meaning than this. Many persons use it to mean treatment by means of complex synthetic chemical compounds, as opposed to treatment by means of medicinal plant extracts and other substances which occur in nature. This, according to Professor Bernardt Nocht, is not the true meaning of the word; he considers that the word implies treatment directed against the causative organism of the disease rather than against the symptoms which are the reaction of the human body towards the organism. This latter is probably a better definition as it reflects more truly the ideals of Ehrlich, the father—rather than the inventor—of chemotherapy. This definition allows the inclusion of such drugs as quinine and the cinchona alkaloids, as they are used mainly for their action against the specific organism and not as febrifuges, but it excludes syn-

thetic compounds, such as aspirin, which is used almost exclusively for its analgesic, antipyretic and chologogic properties.

To the average practitioner working in Europe and North America, chemotherapy means only one thing, that is salvarsan and the allied arsenicals, but to the worker in the tropical zones it has opened up a much wider field of vision. Even the synthetic arsenicals themselves have a wider applicability as they are not only specifics for syphilis, a disease which has a very high incidence in most tropical countries, but also for other spirillar (spirochaetal) diseases such as yaws, relapsing fever and rat-bite fever. In the treatment of all protozoal diseases chemotherapy plays an all-important part. The drugs employed aim at the destruction of the causative parasite, and in nearly every instance these drugs are synthetic ones; the principal exception to this generalisation is quinine, and the allied alkaloids. Malaria is outstandingly the most important disease in tropical medicine and until quite recently we have been dependent for its treatment on the cinchona alkaloids; these are not synthetic drugs although they are administered with the object of destroying the plasmodium, the causative organism of the disease. Now, however, another drug has come into use; this drug is a synthetic compound and therefore a true child of chemotherapy. It is true that extravagant claims have been made for Plasmochin, but there now appears to be little doubt that in the treatment of benign tertian malaria it is very definitely superior to quinine. At present the cost of this compound stands in the way of its universal substitution for the cinchona alkaloids, but further research into the methods of preparation will probably make it possible for the manufacturers to place it on the market at a price comparable to that of quinine. Besides the comparatively high price of this compound it has other very distinct drawbacks; certain very definite toxic symptoms have been reported following its administration so that it has to be given cautiously and under very strict medical supervision, and it has no action whatsoever on the asexual forms of the parasites of malignant tertian malaria. As has been pointed out many times, the discovery of Plasmochin must be looked upon not as the final but as the first successful step in the attempt to prepare a synthetic compound for the eradication of malaria. One cannot for a moment suppose that this was the first compound that the inventors stumbled upon which had any effect on the plasmodium and we must admire their self-control in waiting until they had discovered one which had definite advantages over quinine. We hope that they will now go further and produce some compound which not only has a destructive action on the asexual forms of *Plasmodium falciparum*, but also lacks the toxic action of Plasmochin.

Probably chemotherapy's most dramatic triumph has been in the treatment of kala-azar.

In syphilis and many of the other diseases referred to above various other remedies are available and have been employed with considerable success for a number of years, but until intravenous antimony tartrate was used in the treatment of kala-azar the disease was for all practical considerations a fatal one. Now a cure can be produced in at least 95 per cent. of patients by a course of injections which can be completed in as short a time as a week in many instances, and by the use of a drug the cost of which is by no means prohibitive. In this connection we deliberately used the word kala-azar and not leishmaniasis, because although success has been claimed for the treatment of other forms of leishmaniasis with the various antimony compounds the results of treatment have not been so dramatic as in the case of kala-azar; in the treatment of oriental sore, in particular, other means of treatment are still employed and claimed by some as superior.

Except in the treatment of syphilis, chemotherapy is employed very little in the treatment of diseases of the temperate zones. Gold compounds have been used in the treatment of tuberculosis but with no very startling success; the lead treatment of cancer has apparently been successful in some hands, but it has not been hailed by the majority of workers as a great advance in the treatment of this deadly disease. When one remembers what profound changes can be produced in the human body by the introduction of a few doses of some synthetic compounds, for example by the injection of certain of the pentavalent antimony compounds, one wonders whether it will not be chemotherapy which will rescue the human race in their struggle against the two most serious universal enemies, cancer and tuberculosis.

There is no colour in the statement made by anyone. The police are required to give information of any cases of cholera to the medical authorities, and special measures may be put into force for plague—a disease

(ii) Only original papers, that is to say papers which have not already been read or published in the same or similar form, will be accepted. Not more than two papers will be accepted from any one contributor.

(iii) Papers will not be accepted from individuals who have not paid their subscription. (The General Secretary has asked us to particularly bring this matter to the notice of our readers.)

(iv) Papers must be sufficiently short to be read in 20 minutes. It takes 3 minutes to read a page of foolscap intelligibly, apart from diagrams, slides, etc. (Papers should not, therefore, exceed 7 pages of typed foolscap.)

(v) Papers must be accompanied by 3 typed copies of an abstract of the paper. This abstract must not exceed 200 words, and should not contain any formulæ or diagrams. *Papers not accompanied by such abstracts will not be accepted.* (It is not fair on members of the Congress not to have due notice from the programme of what the paper is about.)

(vi) All diagrams, tables, pictures, etc., should be reduced to lantern slides, or enlarged to posters corresponding in type to 6½ x 9 Snellen.

(vii) Authors should not contribute accounts of their papers to the local lay press. (It is hoped that it will be possible to arrange for a daily precis of the proceedings in the Medical and Veterinary Section to be sent to the press officially by the President of the Section.)

Will our readers kindly take this notification as the first official intimation with regard to the 1930 Congress? We trust, further, that the members of the medical and veterinary professions in Allahabad will co-operate to make the 1930 Congress a successful one.

There are three classes of members of the Indian Science Congress; viz:—
of the problem... members; annual subscription,
Health weeks, baby and child health, and the like.

Calcutta School of Tropical Medicine and Hygiene, Central Avenue, Calcutta, at an early date.

The *Transactions* of the Seventh Congress of the Association, held in Calcutta in December, 1927, are in an advanced state of preparation, and it is hoped that they will be published at an early date. The first volume has just been received for review.

THE INDIAN HONOURS LIST. 1st March, 1929.

THE following are the names of medical persons in the Indian Honours List of date the 1st March, 1929. We would offer them our congratulations.

C. I. E.

Licut.-Col. C. I. Brierly, Chief Medical Officer, North-West Frontier Province.

Licut.-Col. R. E. Wright, Superintendent, Government Ophthalmic Hospital, Madras.

Licut.-Col. H. H. Broome, Principal, King Edward Memorial College, Lahore.

Mr. H. T. Holland, Medical Missionary, Baluchistan.

C. B. E.

Licut.-Col. J. K. S. Fleming, Deputy Director-General, Indian Medical Service.

Knighthood.

Khan Bahadur N. H. Choksey, Medical Practitioner, Bombay.

Kaisar-i-Hind Medal (First Class).

Mr. Davys, Assistant in the Military Food Laboratory, Kasauli.

Mrs. Chute, Canadian Baptist Mission Hospital, Akidu, West Godavari District.

Rev. E. H. Sharpe, Superintendent, Purulia Leper Asylum, Bihar.

Mr. N. M. E. Banorawala, Principal Medical Officer, Bikaner State.

Kaisar-i-Hind (Second Class).

Mrs. Simpson, Red-Cross, Bengal.

Mrs. Siddons, Private Medical Practitioner, Central India.

Dr. Gama, Superintendent, Lady Dufferin Hospital, Patiala.

Rai Bahadur.

Mr. Haralal Singh, First Assistant Chemical Examiner, Government of Bengal.

Thakur Sheo Baran Singh, Officiating Civil Surgeon, United Provinces.

Khan Sahib.

Subedar Maula Bakksh, Senior Sub-asst. Surgeon, Punjab.

Rai Sahib.

Mr. Manni Lal Shukla, Medical Officer, Jail and Police Hospitals, Cawnpore.

Mr. Upendranath Roy Choudhuri, Jailor, Central Jail, Gaya.

Mr. Nripendranath Gupta, Medical Practitioner, Muzafferpur.

Mr. Jotindra Kumar Sen, Second Medical Officer, Sadar Hospital, Purnea.

FOURTH IMPERIAL SOCIAL HYGIENE CONGRESS, 1929.

DELEGATES from all parts of the Empire representative of the Dominion, Indian and Colonial Governments as well as health and education authorities, universities and social

organisations, will assemble in London for this year's Imperial Social Hygiene Congress.

The Conference, the fourth of its kind, is being arranged by the British Social Hygiene Council, of which the Marquess of Linlithgow is President with the support of Mr. L. S. Amery, M.P. (Secretary of State for Dominion and Colonial Affairs), Viscount Peel G.B.E. (Secretary of State for India), and Mr. Neville Chamberlain, M.P. (Minister of Health).

The proceedings will extend from July 8th to July 12th, and wide importance is likely to attach to the discussions.

Ten sessions will be held in all, and the programme includes a review of the whole international situation with regard to sex diseases. Papers will be submitted by well-known authorities on practically every phase of the social hygiene problem. One subject to which particular attention will be given is the development of the campaign for the prevention and cure of disease by education and enlightenment, and much interest will also centre in the debate which will take place relative to the effect of infection on industrial efficiency.

The Congress will also consider, among many other questions, the best means of organising and administering treatment centres, methods of propaganda in different communities, the relation between sex disease services and other public health services, such as those concerned with maternity and child-welfare, and methods of securing the co-operation of parents and teachers so that the rising generation may be taught a sense of responsibility in regard to sex conduct.

Those who are likely to be in London next July, and who are desirous of attending the Congress should write for information to the Secretary, British Social Hygiene Council, Carteret House, Carteret Street, London, S. W. 1.

CAMBRIDGE UNIVERSITY DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

WE have received from the University of Cambridge a copy of the regulations for the University Diploma in Medical Radiology and Electrology, and hope that the existence of this Diploma will become widely known to our readers. A considerable number of men in the Indian Medical Service have taken the Diploma in the past, and the Committee are desirous that the facilities offered at Cambridge for the study of medical radiology should be more widely known. The following is an abstract of the regulations:

General Regulations.

(1) Candidates for any examination leading up to a Medical Diploma are required to send their names to the Registry of the University, together with the necessary certificates, not less than three weeks before

the beginning of that examination and to pay at the same time the fee prescribed for admission or re-admission to it.

(2) An examination in each of the Medical Diplomas shall be held once, or if the Special Board for Medicine shall think it expedient, twice a year.

(3) The examiners shall publish a list of the names of successful candidates in each part of the examination in alphabetical order, but are empowered to place a mark of distinction against the name of any candidate who, in their opinion, has shown special proficiency either in Part I or in Part II of the examination.

Special Regulations for the Diploma in Medical Radiology and Electrology.

(1) Every candidate shall be required to pass an examination and to submit for the approval of the Committee a thesis composed by himself.

(2) The Examination shall be in two parts. In Part I the subjects shall be (a) Physics and (b) Electro-technics; in Part II (a) Radiology and (b) Electrology.

(3) Before admission to Part I a candidate shall produce evidence that he holds a medical qualification approved by the Committee and shall submit certificates showing that since obtaining that qualification he has diligently attended during three months, (a) a course of lectures and practical instruction both in Physics and Electro-technics, and (b) an introductory course of clinical instruction in Medical Radiology and Electrology.

(4) Before admission to Part II a candidate shall produce certificates showing (a) that since completing the requirements for admission to Part I he has for three months both received clinical instruction and attended clinical practice in the radiological department of a hospital, with not less than 200 beds, approved by the Committee, (b) that he has studied Medical Radiology and Electrology for not less than six months in all, and (c) that he has held his medical qualification for not less than a year.

(5) The thesis, to be submitted by a candidate after passing Parts I and II, shall be in the form of a critical report with notes upon six cases either in Radiology or Electrology or in both these subjects and shall illustrate various methods of diagnosis or treatment. The thesis shall be sent to the Registry together with certificates; (a) that the candidate has, since passing the examination for the diploma, held for three months a clinical clerkship or similar appointment in a radiological department approved by the Committee, and (b) that the cases described by the candidate in his thesis have been examined and studied by him under the supervision of the person signing the certificate.

(6) In exceptional circumstances, a candidate who before admission to Part II produces satisfactory evidence that he has for at least three months held a responsible post as a radiologist approved by the Committee previously to the six months' study of Radiology and Electrology prescribed as a qualification for admission to Part II, may be exempted by the Committee from the requirement of 5 (a), and if so exempted shall be required to submit a thesis composed by himself on a subject previously approved by the Committee instead of the thesis prescribed in 5 (b).

(7) Each thesis shall be examined by two of the Examiners for Part II, who shall have power to require the candidate to present himself for an oral examination if they think fit to do so.

(8) All certificates of attendance at courses of instruction and clinical practice shall be signed by a person whose signature for that purpose has been approved by the Committee.

(9) Candidates before admission to either part of the examination shall be required to pay a fee of ten guineas and to pay a further fee of four guineas on submitting their thesis.

(10) The short title of the Diploma in Medical Radiology and Electrology shall be D. R. M. and E. (Camb.).

Course of Study for the Diploma.

The Course of Study for the Diploma extends over a period of not less than nine months.

The Course of Study embraces (1) a Lecture Course with practical work; (2) Clinical Instruction.

The Lecture Course:—

Part I.—(a) Physics; (b) Electro-technics.

Part II.—Radiology and Electrology.

Syllabus of Subjects.

PART I.

(a) PHYSICS.

Electrostatics. Electric Currents. Electromagnetic Induction. Radiation. X-rays. Radio-activity. Secondary rays excited by alpha, beta and gamma rays. Transformation of Radio-active substances.

(b) ELECTRO-TECHNICS.

Production of currents, direct and alternating. Sources of supply. Construction and action of motors and dynamos. Photography.

A knowledge of Physics equivalent to the first medical examination is expected on the part of candidates entering for the above course, and they are recommended to obtain supplementary instruction by attending a course in elementary physics.

PART II.

(a) RADIOLOGY.

General anatomy and Histology with special reference to Radiology. Morbid Anatomy with special reference to Radiology. Radio-diagnosis. Apparatus used in Radiology. Radio-therapy. X-ray Therapy. Forms of light and heat Treatment.

(b) ELECTROLOGY.

Electro-diagnosis. Electro-therapy.

Courses for the Diploma in Medical Radiology and Electrology.

Courses for Part I will be given simultaneously in Cambridge and London from October to December as follows:

CAMBRIDGE.

(a) Lectures and Practical work in Physics at the *Cavendish Laboratory* by G. Stead, M.A., University Lecturer in Physics as applied to Medical Radiology.

(b) Introductory course in Medical Radiology and Electrology in the *Radiological Department, Medical Schools*, by A. E. Barclay, O.B.E., M.A., M.D., D.M.R.E., University Lecturer in Medical Radiology and Electrology, and H. M. Meyrick Jones, M.D., B.S. (Durham), M.R.C.S., L.R.C.P.

LONDON.

(a) Lectures and Practical work in Physics at the *Middlesex Hospital* by Professor Sidney Russ, D.Sc. and at *King's College* by B. L. Worsnop, B.Sc. (These two courses are alternative.)

(b) Introductory course in Medical Radiology and Electrology at the *British Institute of Radiology* by J. Muir, O.B.E., B.Sc., M.B., Ch.B., and E. P. Cumberbatch, M.A., M.B., B.Ch.

The courses in Cambridge are open to non-members of the University, subject to the condition that their names are enrolled for the purpose at the Registry of the University and that they pay a fee of one-and-a-half guineas in respect of each quarter during which or any portion of which their names are so enrolled (*Ordinances*, 1927, pp. 69, 70).

Courses of lectures and clinical instruction for Part II will be given in London from January to March by lecturers appointed by the Educational Committee of the British Institute of Radiology.

Applications for information respecting the courses in Cambridge should be addressed to G. Stead, M.A., at the *Cavendish Laboratory*, Cambridge.

Applications for information respecting the courses in London should be addressed to the Director, British Institute of Radiology, 32, Welbeck Street, London, W. 1.

The following hospitals in London are recognised by the University of Cambridge for clinical instruction in the Radiological and Electrical Department: St. Bartholomew's; St. Thomas'; Charing Cross; St. George's; St. Mary's; Guy's; King's College; London; Middlesex; University College; Westminster; Royal Free; Cancer Hospital; Brompton (Chest); Queen Alexandra Military Hospital, and Royal Army Medical College; Prince of Wales' Hospital, N.E.; West London Post-Graduate College.

Examinations will be held at Cambridge as follows:

Part I—January and April.

Part II—April and July.

Fees.

Composition fee covering lectures and practical work for Parts I and II, and three months' clinical instruction in the radiological department of a recognised hospital ..	£	s.	d.
..	47	5	0
Fee for Part I of the Examination ..	10	10	0
Fee for Part II of the Examination ..	10	10	0
Fee on presentation of a thesis ..	4	4	0

"ALL-INDIA MEDICAL CONGRESS," 1928-29.

RESOLUTIONS TO BE MOVED IN THE BENGAL LEGISLATIVE COUNCIL.

1. Mr. Kiran Sankar Ray, Mr. Nalini Ranjan Sankar, Mr. Amarendra Nath Ghose and Dr. Kumud Sankar Ray.—"This Council recommends to the Government that the constitution of the Governing Body of the State Medical Faculty of Bengal be formed as follows:—

(a) One representative to be elected by the Senate of the Calcutta University;

(b) One representative from each of the medical institutions affiliated to the Calcutta University or any other University in Bengal;

(c) One member to be nominated by the Local Government.

(d) Three non-official members to be nominated by the Bengal Council of Medical Registration from registered practitioners of not less than 10 years' standing, of which not more than one is to be nominated from amongst themselves.

(e) Three members to be elected from the teaching staff (including Professors, Asst. Professors, Lecturers, Demonstrators and Clinical Lecturers) by rotation from each non-official institution recognised by the Council of Medical Registration as eligible to train and send up students for their Licentiate-ship or Membership Examination of the State Medical Faculty of Bengal.

(f) Three members to be elected from the teaching staff (including Professors, Asst. Professors, Lecturers, Demonstrators and Clinical Lecturers) by rotation from each of the Government institutions recognised by the Council of Medical Registration as eligible to train and send up students for the Licentiate-ship or Membership Examination of the State Medical Faculty of Bengal.

(g) Three members to be elected by the registered practitioners of 10 years' standing—

(i) one from the British qualified practitioners of 10 years' standing;

(ii) one from the M.B.'s and L.M.S.'s of the Calcutta University of 10 years' standing;

(iii) one from the L.M.F.'s of the State Medical Faculty of Bengal of 10 years' standing; and

(h) The President is to be elected by the governing body from amongst their own members."

2. Mr. Surendra Nath Biswas.—"This Council recommends to the Government to provide in the next budget a capital grant of Rs. 1,00,000 to the Calcutta Medical Aid and Research Society for the construction of a Phthisis Ward."

3. Mr. J. Campbell Forester and Mr. H. S. Suhrawardy.—"This Council recommends to the Government that Rs. 5,00,000 spread over two years be allotted to the Jatiya Ayurbijnan Parishad (half in the next budget and the other in the succeeding budget) in the form of a capital grant for removing its school (National Medical Institute) from Maniktola to Entally and converting the whole premises at Maniktola into a Beggars Hospital."

4. Mr. Surendra Nath Biswas.—"This Council recommends to the Government to provide in the next budget a capital grant of Rs. 4,00,000 to the Jatiya Ayurbijnan Parishad for acquiring land and construction of school buildings for The National Medical Institute and development of the National Infirmary."

5. Mr. Kiran Sankar Ray, Mr. Amarendra Nath Ghosh and Mr. Nalini Ranjan Sirkar.—"This Council recommends to the Government to remove the special exemption enjoyed by the Government Medical Schools from being required to be recognised by the Council of Medical Registration, Bengal, in the first instance before permitting their students to sit for examinations conducted by the State Medical Faculty of Bengal as is required in case of non-official medical institutions."

INFAMOUS CONDUCT.

ONE of the subjects discussed by the Conference (All-India Medical Congress) was the question of medical ethics. A resolution was passed on the question of "infamous conduct" in discharge of professional duties. The Conference unanimously resolved that the ethical rules applicable to England were not suitable for India and that the executive committee of the All-India Medical Association, which is to be formed, should be requested to draw up a code of medical ethics and submit the same to the next annual conference.

SPECIAL ARTICLES.

OPHTHALMOLOGY IN RELATION TO RESEARCH.*

(Being the presidential address to the Medical and Veterinary Research Section of the Sixteenth Indian Science Congress, held at Madras in January, 1929.)

By R. E. WRIGHT, M.D.,

LIEUTENANT-COLONEL, I.M.S.,

President of the Section, and Superintendent, Government Ophthalmic Hospital, Madras.

LADIES AND GENTLEMEN,

As you are probably aware, I have been appointed at the eleventh hour to fill the place of Lt.-Col. R. Knowles, originally elected as President of the Section. I can only regret—with you—that he is not here to-day to do justice to the chair I occupy. This section heretofore has been almost confined to the consideration of research of one type or another and it is but fitting that a research worker should preside over it. It may, therefore, seem out of place that a clinician like myself should venture to address you although I had at one time the privilege of belonging

* Published by kind permission of the Secretary and Council of the Asiatic Society of Bengal.

to the Bacteriological Department, and have always tried to keep in touch with medical and veterinary research in this country. As my energies have been for a long time confined to work in the field of ophthalmology, it will not surprise you if my address deals chiefly with this subject in its relation to research.

RESEARCH ORGANISATION IN INDIA.

Whether in the field of medical or veterinary science, the members of this section and our colleagues throughout the world are all potentially or actually research workers; and although the term research is now most frequently used in a somewhat special and limited sense, which does not even convey the same meaning to all of us, it should not necessarily be so restricted. When I first came to India organised research was almost confined to a small body of workers who devoted their energies to investigations in connection with bacteriology, immunology, entomology, protozoology, and parasitology. The nuclei round which these activities for the most part developed, were the centres for the investigation and prevention of smallpox, plague, rabies, snake-bite, rinderpest and surra. Looking back now one might be inclined to consider that we brought very heavy weapons to bear on rabies and snake-bite, which are comparatively unimportant economically; but the machinery was such that the individuals employed found no suitable environment for launching forth into the investigation of the huge problems in connection with malaria, kala-azar, hookworm, cholera, water contamination, the dysenteries, the less understood fevers peculiar to India, and the many contagious diseases of animals. Before this organised research started there were, of course, many distinguished scientific workers carrying out isolated investigations of the utmost importance. The same is true to-day, because it is impracticable and undesirable that there should be universal direction and control. It is important, however, that our researches should have international connections so as to secure the corrective of universal criticism. In the very early days some magnificent pieces of individual work stand out. It would be invidious to mention names, as many of those who figured so prominently in the world of tropical research are still amongst us. Sir Pardey Lukis made a great effort to co-ordinate medical research in India as a whole, and gradually an organised department was established. This, at first, was somewhat watertight, but by degrees a liaison was established between the public health services on the one hand and the clinical services on the other. The Bombay Bacteriological Laboratory at Parel, now known as the Haffkine Institute, played a large part in uniting the pure laboratory worker with the clinician, and the founding of the Calcutta School crowned the movement and established direct contact in a most suitable environment. Our provincial public health services are linked up with each other, and with the international health problems through the Public Health Commissioner, who keeps the Office Internationale d'Hygiene Publique, and the League of Nations Health Department in touch with India, and who also is closely identified with health activities in the Far East, we still look forward to the establishment of a powerful school of hygiene. It is said that such a school is destined for Calcutta, let us hope that the day is not far off when it will materialise and rival in vitality the School of Tropical Medicine. We may, however, congratulate ourselves that in the last twenty years the different types of work and the workers have been brought into more intimate contact. Now the individual investigator, whether engaged in the hospital clinic, in public health or veterinary field work, or in the laboratory, is able to establish co-operation with others who are willing to place their special facilities or knowledge at his disposal in order to enhance his endeavours.

The medical, veterinary and agricultural departments have come nearer, and some, at all events, realise the

vast importance of a still more intimate association in connection with food problems,—both human and animal,—and the public health. But this is not sufficient. Investigations into the causes of disease in man and animals is so intimately related that it is hard to conceive of a medical worker being in a position to prosecute his researches with any great profundity without a good general knowledge of what has happened and is happening in the veterinary field, and *vice versa*. There are some medical men, and not a few of the laity, to whom veterinary work appears to suggest little more than the treatment of sick cattle and dogs, or the granting of certificates for horses. A study of current veterinary literature would convince such persons of their lamentable ignorance. In bacteriological research particularly, the two sciences are so intimately bound up as to be inseparable. I have personally always enjoyed the fullest co-operation from my veterinary colleagues, and am indebted to them for much help and inspiration.

THE ULTIMATE OBJECT OF OUR RESEARCHES.

If then we regard the individuals of the Medical and Veterinary Departments as research workers in greater or lesser degree, what is the object of our combined efforts, what is the "big ideal?" Ultimately, it is the advancement of the welfare of mankind. Darwin says, "Man, like every other animal, has no doubt advanced to his present high condition through a struggle for existence consequent on his rapid multiplication; and if he is to advance still higher, it is to be feared that he must remain subject to a severe struggle. Otherwise he would sink into indolence and the more gifted man would not be more successful in the battle of life than the less gifted. Hence our natural rate of increase though leading to many and obvious evils, must not be greatly diminished by any means." Again he says, "Important as the struggle for existence has been and even still is, yet as far as the highest part of man's nature is concerned there are other agencies more important. For the moral qualities are advanced, either directly or indirectly, much more through the efforts of habit, the reasoning powers, instruction, religion, etc., than through natural selection; though to this agency may be safely attributed the social instincts, which afforded the basis for the development of the moral sense."

"The high standard of our intellectual powers and moral disposition is the greatest difficulty which presents itself, after we have been driven to this conclusion on the origin of man." Since then Elliot Smith and others have shown us that man's intellectual supremacy is due to the expansion of the brain in connection with vision. "Smell was the foundation upon which the neopallium was begun, and upon the distance-receptor vision it attained its highest perfection in man." (Parsons). Elliot Smith says, "One could say with considerable confidence that the essential fact which brought about the emergence of man's distinctive qualities of mind depended, in the last resort, on the cultivation of the enhanced powers of conjugate movements of the eyes"; and again, "The acquisition of a macula was dependent on these powers of conjugate movement." Keith (1925) remarks, "One of the greatest services rendered to anatomy by Prof. Elliot Smith was the clear proof he gave, fifteen years ago, that the evolution of bifoveate vision was the result of sight ousting smell as the dominant sense."..... "It was clear that the superiority of man's vision lay, not in the kind of eye with which he had been provided, but in the brain which had grown up behind his eyes." This state of brain evolution,—which, phylogenetically under the influence of natural selection was determined by increased reliance on vision acquired by the lemurs, and, making its appearance at an early stage, (Eocene), determined the branching off of the true primates,—differs only in the higher and lower types of existing man, in those intellectual, social, and moral qualities above mentioned. These have appeared, not in the course of natural selection, but in the modified or controlled state of social

existence which man has adopted as the result of the acquisition of knowledge and reasoning. The elaboration of man's brain in his controlled evolution is to our research activities like the climbing of a mountain. As each higher level of intelligence is attained, so we are enabled to perceive and understand the activities at a lower level, which is impossible to those below. At every step the climber is only partially aware of what is happening in his own contour; if he would appreciate fully what is happening at this level he must get higher. So our intelligence strives in vague theorising after the view obtainable from the summit, not quite so blindly after the point just above us, which, after a time we make good, by the aid of a foothold here, or a handhold there, such as a new hypothesis in physics or discovery in chemistry. But the climber must have an appreciation of higher things, and aspire to reach them, not losing perspective and wandering aimlessly in his own contour, without recognising valuable aids, nor giving, nor receiving, help which would lead him upwards. During this period of controlled evolution, medical and veterinary sciences, (with the sciences on which they depend, and to which they are related), exercised a most important influence, but vision continued to play the prominent part in the evolution of man's brain. From the simple relief of human suffering and preservation of the individual life at one end of the horizon, to the higher flights of sociological endeavours,—into which our particular sciences imperceptibly merge,—and the national, and international machinery for the eventual improvement of man's lot, at the other, there is a caravan of individual and collective effort. It is impossible to foresee what the effect of all this control will be on the nation or on the race. Our veterinarians have been well aware for many years of the possibilities of improving stock by selection. This is not such a simple procedure as it might appear for many reasons, amongst others the interference with fertility under more highly domesticated conditions of life. Man, however, in his own case, far from synchronising with natural laws such as those which determined his appearance, has evolved those practices, arts and sciences, which heal the cripple, foster the undesirable, make the conditions for the transmission of hereditary diseases more favourable, and handicap the progress of the more highly developed mental and physical types. All life is preserved,—good lives and bad,—and all agencies which are destructive to life are attacked; in spite of the fact that under natural conditions multiplication tends to outrun the food supply, and that there is only room for a limited number. Are we fostering a deterioration? Is it all a mistake? How does one reconcile the preservation of *all* human life, the suppression of disease, the control of birth, and the elimination of war with the ultimate production of the best human machines? There are signs of disquietude, national and racial. We have periodic endeavours to eliminate undesirables. One European State has approved of the sterilisation of certain of the unfit, and the propagation of the mentally defective is limited, and may soon be controlled. America, awakened to the fact that her desirable racial types were being crowded out by the undesirables, introduced the quota. The position was even worse than that of Glasgow, where, apart from the undesirability of the actual invasion, the immigration of an Irishman, as Dr. Crew points out, may of itself prevent the birth of a Scotsman. It is admitted that the best racial types tend to commit race suicide. It may even be that those who apply the details of medical, veterinary and general research to the formulation of sociological laws, and otherwise tamper with the problem of population and genetics, may make such mistakes as to obliterate completely the highest products of man's evolution.

With such ideas in one's mind, it is somewhat comforting to turn to Sir G. Newman's reports for England and Wales, and realise that during the last forty odd years in a community moderately disciplined, and partially educated in matters of hygiene, the disease

rate has diminished, the average duration of life has been prolonged, conditions of living have improved, the birth rate has fallen, and infant mortality has decreased, although the population during these years has outgrown the indigenous food supply. Instinctively we take it for granted, that, in the kaleidoscopic vista of controlled evolution, the part we are playing in the elimination of disease and suffering, and the betterment of the conditions of human life, must necessarily repercuss on the evolution of the brain, and eventually enable man to guide human destiny along an ascending plane.

THE GENERAL NATURE OF OUR ACTIVITIES.

As man's eventual welfare is ultimately dependent on the further development of his brain, this is the axis round which our activities in medical and veterinary science revolve. Let us consider some of the ways in which the various members of the medical and veterinary professions employ themselves. For the most part they can be grouped according to whether their activities are mainly concerned with curative medicine and clinical investigation, laboratory investigation, or hygiene and public health, all of which are interdependent. We need hardly concern ourselves with the unborn child, but the expectant mother figures prominently in the public eye, and the toxæmias of pregnancy, and the high maternal mortality rate, are causes of the greatest concern to the obstetrician today. The new-born child comes immediately into the purview of some of the most elemental and far-reaching investigations of modern medical and veterinary science, namely those in connection with foodstuffs and radiant energy. Here the medical and veterinary sciences go hand in hand and they must of necessity link up with the sister department of Agriculture. The economic importance of research in connection with nutrition, diet, and essential food factors in India is obvious, but it is only comparatively recently that it has developed a real scientific and practical side. McCarrison has done much to attract the agriculturists and veterinarians, and we hope for the greatest benefits from this line of research when co-operation is established between the various departments concerned.

As human beings develop and become liable to attack by the vast army of diseases, their conditions of life become the subject of attention from the three groups above mentioned, the clinician, who represents curative medicine, the exponent of hygiene and public health, representing preventive medicine, and the laboratory investigator, who, often too widely removed from his colleagues, pursues those more experimental and intensively detailed studies which are calculated to supply the key to the solution of the others' difficulties. Curative medicine cannot be divorced from clinical research, and although there are some who hold that curative medicine is a luxury of civilisation, still, the human machine will need repairs as long as humane motives prompt the healing art, and the dictates of the instinct of self-preservation hold sway.

Systematised clinical medicine is the backbone of our professional activities. One has only to think of the great recent advances in plastic and brain surgery, or of that in connection with the air passages and transplantation, to realise the value of careful clinical investigation and to appreciate that surgery is not yet up against a dead end. But even now, just as when the new era of surgery dawned, its best efforts are based on the findings of the laboratory. It is to organised clinical investigation, in co-operation with the practitioner on the one hand, and the laboratory worker on the other, that we must look for rapid advances. Some of the highly organised clinics in America such as the Mayo Clinic, the Johns Hopkins Hospital, and in Canada the McGill University, have been steadily turning out systematic co-ordinated research work for years. The comparatively recent introduction of whole time clinicians and hospital units in the English schools, shows that a need of co-operation in education and clinical research was felt. Unorganised clinical research

depends on the periodic appearance of giants in science. The recent investigation in connection with liver treatment in pernicious anemia in the United Kingdom, shows how a number of different clinical centres all over the country can work in harmony with a directing head. In the investigations into chemotherapy, pharmacology and organotherapy we see some of the finest organised clinical work of recent years. The chemotherapist has practically filched one of the three great chronic granulomata from the surgeon, and launched a determined attack on the other two. On the other hand one of the greatest disgraces to our science is the way in which the inquiry into organotherapy has been allowed to drift into the hands of vendors who exploit the general public. These are encouraged by empiricists in the profession, who might do so much to help real research if a collective effort were organised. You are probably all inundated with pamphlets and circulars by mail from overseas, the bulk of which are got up to advertise organotherapeutic products. If the part of the contents which relates to ophthalmology is an index of that which appertains to other branches of medical science, the responsible firms ought to be penalised. One would like to see a tax on such advertisements, as a protection to the public and the profession.

It is in the laboratory that the ultimate cause of disease is tracked down, and accurate means of diagnosis elaborated. Here the pure research worker finds his natural habitat. Up to now, in India, he has for the most part engaged himself with the ultimate problems which face the clinician and public health worker, and has been the base of supply, as it were, for these two in their attack on disease. But as there must be research in all branches of medical and veterinary science, the efficient laboratory system must have representation in all the roots of our sciences. Ideal research laboratories should therefore give a home to those subdivisions of research which deal with clinical medicine and surgery, nutrition, pharmacology, organotherapy, hygiene, and so on, in addition to those commonly associated with such institutions. The part played by our sciences in public health has made enormous strides of recent years. The work of the public health department, has, in association with the Indian Research Fund Association, made itself felt in international medical science. One can get a good general idea of the nature of our activities by contemplating the scope of the Proceedings of the Far Eastern Association of Tropical Medicine and Hygiene. As Col. Megaw has written, it "is now regarded as the most valuable symposium of tropical medicine which has ever been held."

PERSPECTIVE AND CO-OPERATION.

The fact that curative medicine is readily marketable is often the undoing of members of the profession from the point of view of the individual pulling his weight in the combine. Provided, however, the clinician does not forget the first essentials of research, accurate observation, careful tabulation, and correct interpretation of facts and figures, he will always be the most important medical scientist to the man in the street, and essential to workers in the other, a little amused at the limitation of his brethren who are engaged in laboratory or public health work. The laboratory research worker who probes into isolated problems connected with the cause of disease, the man who, as he was described to me in the Rockefeller Institute last year, goes on finding out more and more about less and less, has perhaps some excuse for a limited horizon. His immediate effort is not so marketable as that of the clinician, and it is considered that to take his attention off his work, on account of such mere trifles as comparative affluence, is incompatible with research. The more rational view is that the research worker must not only be freed from the petty annoyance of making profit out of his work, but must also be put in such a position of well-being as to allow of his care-free attention. In the best organisations

to-day this object is aimed at, but hardly yet achieved. It is probably true that if scientific research were properly organised and co-operation established,—not in medicine alone, but in the great basic sciences also,—it could wield a controlling power in the world's affairs. At present science as a whole is in the position of the medical laboratory research worker, exploited by those who pick its brains. We were reminded not long ago by His Excellency the Viceroy when speaking on scientific research, that according to one author, the true scientific method includes keeping no secrets, attempting no monopolies, serving no other end but knowledge. No doubt to strive after the highest ideals in life's work is an attribute of the more advanced evolution of man's mind, but one sometimes wonders whether the politicians and the promoters of industry, who are so insistent on the ideal where the scientist is concerned, might not be encouraged to apply the same philosophy in their own spheres, if science had more organised power. One looks back on the ill-feeling in connection with Ehrlich's great researches in chemotherapy and his careful release of 606, and cannot help contrasting it very favourably with the uncontrolled way in which investigators of the properties of ductless glands place immature work in the hands of the big vendors of the refuse of the stock yards.

Diseases vary in what is considered to be their economic importance, and in this connection the Public Health worker comes in contact with employers of labour and the local authority concerned with the good of the people, with politicians, and with nations. Public health has largely become an international affair, and in this we see the nearest approach to the working of medical science for the "big idea." We are all a little inclined to think that our own particular line of action is vastly important, and by contrast, there is a lack of appreciation of the work of others going on around us. For instance an intense ophthalmological research worker in India might easily lose sight of the fact that many of his activities would cease if the Agricultural Department reached a high functional level, or the local authority followed the lead of the more advanced European countries in the control and treatment of venereal diseases. In any case, it might be for him an unpleasant contemplation as whole time employment on refraction work is a very dull occupation. Fortunately there are in the ranks of medicine not a few natural philosophers who from time to time remind us of what are really working towards in our continued, even if partially blind, effort, and stimulate us to read just our perspective.

DIRECTION AND TRAINING.

The most important thing perhaps for the young research worker of to-day to remember is that the mere gathering together of a few facts and presenting them afresh, or the growing or failure to grow some in a test tube, does not constitute research. Amongst the greatest research workers are those who are able to assemble and evaluate recorded facts. The man with the spade may spend hours of toil on a subject which is valueless to himself or anybody else. Direction in research is all important unless the worker is sufficiently trained to choose important lines along which to work. Above all, the modern research worker must have a training which was denied to many of the older members of the medical and veterinary professions, in the essentials,—the bedrock subjects,—physics and chemistry. Most other subjects fade into insignificance as compared with these, and naturally, they go hand in hand with mathematics. An appreciation of the literature is vastly important. The greatest mistake many workers make is in not familiarising themselves with all the available work which was done before on the subject under consideration. Numbers of investigators waste months on a task which they might have avoided had they made a thorough preliminary survey of the literature. It is on deep foundations that the most important researches of the future must be built. The nature of the vital processes, the chemical, physical,

and electrical activities of the living cell, the interaction of the elements of vital tissues, the nature of energy and matter. These are the things of importance in the training of the younger generation. They must be able to use the more advanced teaching in those subjects as a means of interpreting and expressing their observations.

RESEARCH IN OPHTHALMOLOGY ILLUSTRATIVE OF, AND RELATED TO, RESEARCH IN GENERAL.

We have seen that the advancement of the welfare of mankind is our goal, and that this is ultimately dependant on the further development of his brain. Further we have seen that the brain of man reached its highest perfection through the agency of vision. It will not be inappropriate, therefore, if I give you an idea of some of the directions in which scientific investigation in connection with ophthalmology has progressed of recent years. In doing so I shall endeavour to exemplify by reference to this localised, but vastly important field, many of those types of activities with which we are all concerned, and reflect in the mirror of ophthalmological research, the various ways, in which medical and veterinary sciences in general, pursue the ultimate object of our endeavours.

The eye consists essentially of a globular outcrop of the brain which has become invaginated to form a cup, separated from the outside world by a transparent epithelium modified to form an optical system. The neural epithelium is capable of receiving distant stimulation by means of the radio-receptors,—the rods and cones,—so that it is possible for us to form an impression of a source of radiation at an enormous distance, e.g., a star. We can examine this receptive organ during life by accurate methods which we cannot apply to any other part of the body. The ophthalmoscope enables us to obtain a magnified view, (about fifteen diameters), of the finer vessels on the surface of the retina, which, for all practical purposes is the surface of the brain, so that we can observe over long periods the changes taking place in this important system of vessels, from their earliest stages right up to the establishment of gross disease. We are thus enabled to gauge more accurately perhaps than by any other method applicable during life the probable changes which take place in the cerebral vessels. It is not only possible to undertake this histopathological investigation of living tissues, but our observations may be recorded accurately and scientifically by means of photography. The photography of the fundus oculi has now reached a practical stage and this method will be increasingly used in the future to record serial observations of pathological processes. One of the greatest advances in this field has been made by the introduction of slit-lamp illumination in connection with the corneal microscope. As Vögt has said, "with it ophthalmology has entered on a new stage of development." The improved instruments enable us to throw a sharply cut narrow beam of light into the eye, so as to produce an optical section of the cornea and lens, which may be examined with the binocular microscope at practical magnifications up to fifty diameters; (magnifications of over a hundred diameters may be obtained, but are impracticable for various reasons). The study of the eye by this means is known as biomicroscopy or the histology of the living eye. We are enabled thereby to study not only such minute details of cellular structure as the corneal endothelium, but the optical heterogeneity of tissues such as the lens and vitreous is disclosed, and their "relucency,"—as it is called,—is revealed, so that they exhibit a structure which was not hitherto detectable in dead fixed tissues under the microscope. The help which the method has afforded in connection with the investigation of certain conditions, formerly of a doubtful nature, has rendered it indispensable. We owe our advances in this direction chiefly to the researches of Vögt, Kœppe, and Henker. It has been particularly useful in connection with the study of lenticular changes of a cataractous nature.

The subject of cataract has, as you know, occupied a very prominent place in ophthalmological literature, particularly in the field of surgery. The surgical treatment of cataract, however, has probably had more than its share of prominence considering the relative economic importance of the subject, so I shall not do more than mention three of the factors, resulting from the clinical research in technique, which have sprung into prominence of late. They are, the elaboration by Barraquer of the suction pump for removing the lens in its capsule, the adoption of some means of retaining the lips of the section in apposition after operation, and the more extended use of novocaine in obtaining a painless and motionless field of operation. These factors have been prominently before the minds of workers in many of the large clinics of the world, and as may be seen from the literature Madras has not been behind hand. The method of blocking the main trunk of the seventh nerve near its exit from the skull, originally evolved here in the Government Ophthalmic Hospital, and now practised by us as a routine method, is coming into more general use. But research in this department of glorified carpentry is after all but temporising with the subject. As Duke-Elder, one of our ablest ophthalmological research workers of the younger school, has said, "When we as physicians fail to cure, and when we as surgeons lay down the test tube and take up the knife, we are, in so doing, merely confessing our failure as physicists, chemists, and admitting that, as yet, our laboratory is too complicated for us to understand, our reagents too complex for us to manipulate, and our knowledge too fragmentary and inadequate for us to apply it systematically." It is pleasing at all events to know that many prominent investigators are alive to this fact in connection with cataract, and we are now in a position to demonstrate the production of cataractous changes in the eye of the rabbit in a few minutes by isolated infra-red rays, and to observe the process with the corneal microscope. The most important recent work, however, which has been done in cataract is in connection with the chemical nature of lens protein. Lens protein is made up of several components, on the integrity of which its transparency depends. Under certain conditions a change takes place in one or more of these components rendering coagulation more liable to take place. There seems to be a strong school of thought, backed by an immense amount of experimental work in the realm of physico-chemistry, and radio-activity, which ascribes to the action of light on the constituents of lens protein, the first step,—the establishment of the predisposing factor as it were, in the production of cataract, other than complicated cataract. The equilibrium of the auto-oxidation system is interfered with and coagulative changes ensue. It is admitted on the other hand that typical instances of complicated cataract are due to alterations in the fluid available to the lens for its nutrition. The relative importance of these two processes appears to require much clarification. In so far as India is concerned it is probable that a very large number of cataracts labelled "senile" would more truly be styled complicated, and that alteration in the fluids which bathe the lens plays a leading rôle.

Most of you are no doubt familiar with Carrel's work on tissue culture. His original growths from heart muscle are still maintained in sub-culture. It is important for purposes of investigation in vitro to obtain a pure growth, and this is difficult, as it is desirable to use embryonic tissues. To remove the lens from a five-day old chick embryo is not easy, but it is possible. Dr. Kirby, a New York ophthalmologist working under Carrel's direction, has elaborated this technique and thus obtained an absolutely pure mass of actively growing epiblast for culture. The epithelium, which grows well on a sterile plasma surface in embryo juice, does not resemble lens epithelium, it is for example opaque. This fact is of immediate importance to the investigator. One wonders whether it is possible to grow clear lens epithelium. It may be that this line of investigation, in conjunction with

the chemical investigation of lens protein, will yield valuable results.

An entirely different type of investigation is that in connection with the filterable viruses. For many years bacteriologists have been faced with a certain type of acute infective disease which is not associated with a demonstrable cause. One helpful fact emerged in connection with the group, namely, that the virus was filterable in certain cases, and that it is probably an ultra-microscopic living entity. In connection with certain of the so-called filter passers, observations have gradually crystallised into an hypothesis enunciated by Levaditi, that certain of them might be grouped as neurotropic ectodermoses. In this group some of the most informative work has been carried out on the herpetic affections of the eye. Here again we find the peculiar nature of the visual organ rendering material aid to a difficult research. The clinical processes in question are readily studied in the transparent cornea by the aid of the corneal microscope. You will, I trust, hear something of further interest on this subject when our research on the present extensive epidemic of superficial punctate keratitis is presented to the Section.

Investigations in connection with trachoma well illustrate how the cause of an important economic disease may ultimately be tracked down by a laboratory research worker. It had from ancient times given the clinician ample opportunity to demonstrate the futility of his curative methods, till, with the march of civilisation, it was taken out of his hands by the public health worker who dealt with it by segregation,—and that very effectively, as one may gather by the effect of the immigration laws put into force by the United States of America, and from a comparison between its spread in the Egyptian campaign early last century and its control in the late war. It may be too early yet to say definitely that Noguchi has discovered the causative organism of trachoma, and, even if he has, that it will afford a key to the control of the disease, but his work is a magnificent illustration of the adaptation of new methods of technique and procedure in connection with the isolation of a causative organism. Bacteriologists had sometime ago apparently arrived at an impasse; almost everything pathogenic to man that could be grown in a tube, with the limited media and methods available, had been grown. Noguchi, whose untimely death we have to deplore, was one of the pioneers in introducing new conceptions of cultural methods. Certain observers have failed to confirm his trachoma work, but it is doubtful if they have followed his technique. A few days before he sailed from New York for West Africa, Noguchi showed me his cultures of *B. granulosis* on semi-solid leptospira media, and demonstrated the disease produced by mass infection with pure cultures in his chimpanzees. His sections of the disease produced in monkeys were indistinguishable from sections of the human condition. His trachoma research has appeared as a supplement to the *Journal of Experimental Medicine*, and no doubt some of you have seen and admired this last fruit of his labours. Quite recently Prof. Axenfeld gave me to understand that Prof. Linder, who now holds the chair of Ophthalmology in Vienna and of whose bacteriological investigations you have possibly heard, was on his way to the Rockefeller Institute, New York; so the critical examination of Noguchi's work may be awaited in confidence.

The consideration of trachoma naturally leads one to think of the other great economic affections of the eyes. The commonest cause of blindness in England and Wales, according to the Departmental Committee on the Causes and Prevention of Blindness, is ophthalmia neonatorum. Not only is gonorrhœa of enormous importance, but so also is syphilis, competing with congenital defects for second place as a cause of blindness in infancy, accounting for a high percentage of the blindness of adults also. Venereal disease in various forms when looked at from the point of view of interference with human vision, on which our

welfare so largely depends, assumes enormous relative importance. In certain countries maternity training and propaganda in connection with the prophylaxis of ophthalmia neonatorum has brought the attack rate to an apparently irreducible minimum which is still deplorably high. In England the Council of British Ophthalmologists, which exercises such an important influence on all matters touching the sight of the nation, has taken the further improvement of preventive measures in hand. The control of syphilis is progressing rapidly. The whole nature of the disease is ameliorating, and in this we have an example of a condition in which organised curative medicine in the mass, when founded on sure chemotherapy, may prove a better weapon than preventive medicine.

In India it is more difficult to evaluate the chief causes of preventable blindness. In the first place it is not possible to get accurate figures for the serious affections which attack the eye in the first month, year, or age period. Here we have an example of the importance of maintaining adequate returns for the compilation and application of vital statistics. It has been assumed that ophthalmia neonatorum is as important a cause of preventable blindness in India as in England. There are, however, some facts bearing on this assumption which must be considered. Ophthalmia neonatorum appears to be a milder affection in India,—at least amongst the inhabitants of Madras,—than it is in Europe; syphilis of the eye in the first year is not uncommon, and this, together with smallpox, keratomalacia, and the application of irritant remedies account for a relatively large amount of damage to the eyes in the first few years. It is probable that preventable blindness has been vastly reduced in this Presidency by better methods of vaccine production established by Cunningham, resulting in a higher protection rate, but reliable statistics are again necessary to confirm this view. This consideration helps us to appreciate in proper perspective the value of the laboratory worker, and the field worker, to an apparently isolated clinical section of the medical department. It might be a disquieting thought, that the King Institute of Preventive Medicine, Guindy, has perhaps done as much (or more) towards the prevention of blindness as the Government Ophthalmic Hospital, if we did not appreciate the work done by others and the fact that prevention is a more potent factor in the elimination of disease than cure.

Keratomalacia is a condition, the economic importance of which may have been heretofore underestimated, as it is not very uncommon in the early age periods and may mount up by summation of effects to a very important cause of the blindness at all ages in South India. As you know keratomalacia is a familiar affection in ophthalmic hospitals in India,—perhaps most so in Madras. At the last Congress here some of our work at the Government Ophthalmic Hospital on this subject was brought forward. Since that time enormous strides have been made in the realm of deficiency diseases, but we are very far from reducing them to concrete terms of physics and chemistry. In so far as clinical ophthalmology is concerned, we are in the same position now as five years ago. Cod-liver oil is the best all round method of treating keratomalacia. It is marvellous to watch an appalling condition of the eyes (and, of course, the respiratory and alimentary tract in the advanced condition), clear up under this treatment, and this alone.

The importance of combating the six affections due to smallpox, gonorrhœa, syphilis, irritant remedies, trachoma and keratomalacia, on account of their attack on the eyes in early life, is not realised in this country. Intensive propaganda work is urgently required. Money spent in this connection would be better spent than in establishing institutions for the blind, which although humane in intention is a misdirection of the wrong end. The support of the Government has, up to now, been unenthusiastic.

Besides keratomalacia, there are other eye affections which are dependent on the proper relations of essential

food factors and the endocrine glands. We know that sunlight is the activating factor in the production of foodstuffs which are essential in maintaining normality. Both the cow and the grass must be irradiated if the milk is to have its full value. Indirectly we may have the eyes affected via this route, for example, in some of the juvenile cataracts. Von Szily, too, has demonstrated the production of cataract in suckling rats by withholding vitamin A from the mother, the so-called avitamine cataract.

The foregoing considerations lead us naturally to the subject of radiation in ophthalmology. The nature of light is at present in such a state of flux, and constitutes such a complicated problem, that we cannot here consider with advantage its full bearing on our investigations. We presume that life ultimately depends on light. Radiant energy to which the eye is transparent is harmless. It is rays which are absorbed which may damage the eye. These are notably the rays which merge with either end of the visible spectrum, the infra-red at the long end and the ultra-violet at the other. The radiant energy of wave lengths in between, i.e., white light,—which may be split up into its component parts as the visible spectrum,—is for the most part absorbed with the production of visual sensation. If in excess, part of it may be degraded into heat. The absorption of infra-red in greater amount than can be counteracted by the nature of the tissues, gives rise to a thermal lesion. We have seen above that such lesions may be demonstrated experimentally, e.g., cataractous changes in the lens. A concentration of infra-red rays at the macula, such as occurs, for example, during the ritual of sun gazing, or observing an eclipse of the sun without adequate protection, may produce an actual thermal lesion at the macula. The rays of short wave length,—the ultra-violet,—produce abiotic lesions, chiefly of the superficial parts. We do not yet know how far the investigations into the noxious influences associated with the absorption of heat waves and ultra-violet radiation may lead us. In India we are not very much concerned with the abiotic phenomena produced in the eye by ultra-violet radiation, although they are familiar enough at high altitudes. In the plains, however, it may be that the effects of the absorption of the infra-red radiations are of more far-reaching importance than we have any conception of. Duke-Elder has prosecuted the most interesting enquiry into the therapeutic action of ultra-violet light on certain diseases of the eye. The general action of controlled ultra-violet radiation appears to be associated with a raising of the bactericidal power of the blood. The eye diseases which respond best to general treatment appear to be tuberculosis and scrofulous conjunctivitis. For diseases of the cornea he uses a special mercury vapour lamp from which a beam may be thrown on the cornea in such a way as not to impinge on the lens. Various forms of blepharitis, conjunctivitis, and keratitis have been treated with good results. The value of irradiated ergosterol has not yet been established as of value.

One often hears it said that refraction is the "bread and butter" of ophthalmology. This may be so to limited extent, although the examination of the eyes in connection with optical defects, if done properly, is a time-absorbing process. As in many other varieties of medical relief, it is not always done properly. This is very largely determined by the attitude of the general public, and to a less extent by the ophthalmologist. It is not yet generally realised that the eventual well-being of the eyes is very largely bound up with this problem of accurate correction with spectacles, although Edward Jackson,—the doyen of American ophthalmology,—does not leave one in doubt on this point. Given eyes that have some visual acuity, it is essential to obtain the best optical results by means of artificial aids,—for by not doing so, latent disease may be fostered or a liability established. It is significant that,—as noted here by my predecessor Col. Kirkpatrick while observing cataract cases,—it is often in the eye with the greater error of refraction

that a cataractous process first starts. The amount of work done on refraction in the last twenty years is enormous, although not more so than is commensurate with its importance, but except in the special literature it does not attract much attention. It is a difficult study involving basic principles, and research in this connection is not so "flashy" as in the less important operative fields, but fortunately there are those who realise the full value of correcting errors of refraction and muscle balance. In the English-speaking world, we owe a great deal in this respect to Duane and Jackson in America, Maddox and Percival in England, but the disabilities and loss of efficiency due to uncorrected errors of refraction are still not appreciated, even by the members of the profession.

The anatomy of the eye has attracted very considerable attention in recent years. Prof. Arthur Thompson of Oxford has been prominently identified with this movement. His association with ophthalmology was linked with that of Coats, a most distinguished investigator of clinical ophthalmology, who founded the Oxford Ophthalmological Congress. Prof. Thompson is responsible for the beautiful anatomical production, "The Anatomy of the Human eye as illustrated by enlarged Stereoscopic Photographs," and Prof. Whitnall, formerly his Demonstrator, now Professor at McGill University, published a few years ago "The Anatomy of the Human Orbit and Accessory Organs of Vision." Some of you are possibly familiar with Onodi's work on the nasal accessory sinuses, and may perhaps have seen those of his dissections acquired for the Museum of the Royal College of Surgeons. Onodi's work on "The Optic Nerve and Accessory Sinuses of the Nose," was an important addition to our knowledge of the relation between diseases of the nose and of the eye, and, as an applied anatomical study, gave a clear idea of the relations of the nasal accessory sinuses to the orbit. The region of the basi-sphenoid is of the utmost importance to the eye specialist, because the optic nerves are intimately related to the great air cells and to the pituitary fossa, and subject to damage by pathological conditions of either. In connection with this part of the body, investigations by means of radiography have advanced enormously of recent years. The highest standard of radiographic work is essential in making diagnoses in this region, as for instance the demonstration of expansion of the optic foramina. You are probably all aware that in Madras we have the advantage of an excellent service in this respect.

Embryology is a subject which does not at first appear to offer a very fruitful field for ophthalmological research. Yet one has only to read Miss Mann's recent classical contribution to the literature to realise that her observations have thrown considerable light on some clinical problems, e.g., congenital defects. In addition she gives a clear conception of the ultimate nature of the structure of the eye, on which to found rational ideas of pathological processes.

A great deal of work had been published by continental writers but Miss Mann, as the result of her investigations on a unique series of human embryos, produced the first comprehensive account of the subject in the English language.

The research which has perhaps caused the greatest stir in ophthalmological circles is that of Duke-Elder on "The nature of the intraocular fluids" as related to glaucoma. With a more elaborate and delicate technique that has hitherto been considered practicable, he has measured the actual pressure in the retinal arteries and veins, and arrived at an idea as to the pressure variations in the capillaries. The hypothesis is put forward that the aqueous is a dialysate in equilibrium with the capillary blood, that there is no real circulation of the aqueous as previously understood, and that its escape by means of the filtration angle only takes place as an adjusting mechanism when the intra-ocular pressure rises above that in the canal of Schlemm. The vascular bed normally maintains a pressure at which an adequate circulation is

maintained and thermo-dynamic equilibrium is established between the aqueous and the capillary plasma. Variations from this level may occur through, (a) altering the equilibrium level, either by a change in blood-pressure in the capillaries, a change in osmotic pressure between the aqueous and capillary plasma: or, (b) varying the volume pressure inside the eye, by alteration in dilation of the uveal vessels, varying the quantity of aqueous, or varying the volume of the vitreous or lens. Duke-Elder's work has enabled us to rearrange our ideas of glaucoma, and helped those whose working knowledge of chemistry and physics was insufficient adequately to express the phenomena which they had observed to form a clearer conception of the nature of this important affection. So far, however, the effect of these researches on treatment has not made itself felt except in one direction,—namely, that of rapidly reducing the intra-ocular tension by means of intravenous injections of hypertonic saline, so that we are still in the position of having to treat our cases by operation. As most of you are aware it is the operation which Elliot established here in Madras which is used by the majority of surgeons the world over to-day. It is not merely the operation of sclerocorneal trephining, however, but the careful clinical investigations which led up to its adoption, and studies in ophthalmology, especially those in tropical ophthalmology, which have established the reputation of my distinguished predecessor, and linked up the name of Madras with scientific ophthalmology wherever it is practised. The operative treatment of glaucoma is, however, but a temporary phase and a confession of ignorance. Work is gradually accumulating which may at no very remote date bring this appalling disease within the control of the physician. The main subject chosen for discussion at the International Congress of Ophthalmology this year is the non-operative treatment of glaucoma. Here in Madras we have a vast amount of material at hand, but in trying to utilise it we are driven back on that last line of defence—behind which many of our problems take refuge.—the obscurity of the physical and chemical processes involved. Some progress has been made both by the compilation of clinical observations and empirical treatment, and by more exact methods undertaken for us by the Professors of Chemistry and Biochemistry. One fact appears to stand out in connection with certain varieties of glaucoma,—as indeed with certain varieties of cataract,—and that is the association which exists between these diseases and involutionary change. This picture of involutionary change is constantly before the ophthalmologist in India, at least in the south. It is at present impossible to picture its essential pathological processes. It is suggestive that they resemble for example those of chronic anaphylaxis and that the alimentary tract is frequently abnormal. It is obvious that there are numerous milestones on the road which leads from the newly-born apparently healthy child to the grey haired, atrophic skinned, cataractous involution of thirty to forty. Many of them are obscure, but at least some are visible, namely, the consequences of excessive thermal radiation and inadequate food supply near the one end, and a damaged capillary endothelium near the other. There is invariably a summation of chemical and physical insults to the cells of the body as life goes on which finds expression in atrophy, degeneration and death. In South India the lack of energy supplies,—both enteral and extra-ental,—together with the direct and indirect evils of infra-red radiation, are factors which operate conspicuously.

In the field of physiological research, vision has naturally always claimed a large share. One of the most profound and important directions in which much progress has been made of recent years is the relation between the eyes and the labyrinth, and the functions of the eye in connection with the postural reflexes. The decerebrate animal orientates itself in response to forces acting on it, such as gravity, by a reflex mechanism which depends for the most part on the labyrinth, whereby a movement of the head except

horizontally is compensated for by a movement of the eyes. In the neck reflexes, the movements of the head in any direction are accompanied by compensating eye movements. If the cerebral hemispheres are removed, a resting animal orientates itself, and recovers its ordinary posture when aroused, by righting reflexes, acting through the mid-brain and labyrinth. In the monkey, provided the visual cortex remains, the righting reflexes are preserved even after labyrinthectomy. So that in higher animals the eyes can compensate for the loss of the labyrinths, the dominating influence of binocular vision coming into play.

As a final instance of research in connection with the eyes, we may consider the philosophical investigation of that most eminent ophthalmologist, Sir John Herbert Parsons. In his recent work, "An introduction to the theory of perception," we have a magnificent example of synthetic reasoning built up around the phenomena of vision. He hypothecates a biological basis for the phenomena of the higher visual and other perceptual processes, and advocates the development of psychology on a sound biological basis. He traces the genesis of perception from the lower levels phylogenetically where undifferentiated receipts give rise to responses vital to the preservation of the species. With further differentiation certain functions of the nervous mechanism assume a preponderant rôle, e.g., the olfactory apparatus in certain lower animals. The primates have attained their supremacy through the predominance of their visual function. From the human point of view perception appears to be the result of the correlation and integration of many and diverse sensory factors. Head propounded a dual mechanism for cutaneous sensation; a primitive protopathic and a more differentiated epicritic. Rivers applied the same idea to more complex integrations, instincts being essentially protopathic, whilst intelligent control of lower functions is epicritic. Parsons elaborates and modifies this line of reasoning. He hypothecates a dysergetic mechanism on which an epicritic is superimposed, and at a higher level still, "a syncritic mechanism subserved by the cortex cerebri, having the function of integrating epicritic phenomena." He says "Since perception is a phenomenon of consciousness, every inference must be derived from human experience: and since vision is the preponderant modality in the primates and has undergone the highest differentiation, it may be expected to afford especially valuable data. For that reason, and because it has been my own special study for many years, most of this thesis is devoted to that aspect of the subject.....for I am convinced that psychology, as a science can only be developed on a sound biological basis." Consciousness has developed in evolution because of its utility to the animal in sorting out, arranging, and utilising the messages which come in from the various receiving stations. To continue the simile, the man in the street cannot form a mental picture of what goes on in the head office with regard to decoding, retransmission, etc., but he may reasonably presume that it is similar in mechanism to what takes place at the receiving stations with which he is familiar. If he wants to appreciate fully what is happening in the various internal departments, he must not only have had experience in them, but have had the further experience of directing them. To be more technical, it is only by "back stroke" from a higher level of cortical experience that we are able to appreciate fully the nature of phenomena at lower levels. Sir John Parson's treatment of this subject illustrates, in so far as our research activities are concerned, integration at a syncritic level,—to use his own word,—and makes his reader feel the urgent need of accumulating experience of the basic facts of physics and chemistry, so as to utilise them by means of this mechanism in the elucidation of those phenomena which are incomprehensible without their aid.

And now having led you in thought to some of those higher pinnacles of our endeavours, let me conclude this discourse with an anticlimax. In so far as India

is concerned, so long as the mind of the masses remains at such a low level of education in hygiene as it is to-day, we are only knocking our heads against a mud wall in trying to impose western curative and preventive medicine on a large scale. So long as the food supply remains limited, under present hygienic conditions, the population density will be adjusted to its food supply by catastrophic natural means, such as pestilence or famine, rather than by the more orderly proceeding of a fall in the birth rate. India is a magnificent field for medical and veterinary research, and all honest work done in this respect goes to pile up the credit balance placed at man's disposal for own ultimate good, but the results are for the most part inassimilable by the masses in India for want of education in hygiene.

WILLIAM HARVEY'S MESSAGE TO INDIA.

(Being an Address delivered to University College Medical Society, Rangoon, 1928).

By G. R. McROBERT, M.D., M.R.C.P.,

MAJOR, I.M.S.,

Professor of Physiology, Rangoon University.

THREE hundred years ago, in 1628, there appeared from a printing press in Frankfurt, Germany, a small book written in Latin by an English physician and destined to be hailed throughout the world in later years as the foundation of physiology and of all scientific medicine.

The book to which I refer was *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*, (An Anatomical Disquisition on the Motion of the Heart and Blood in Animals) and its author was William Harvey, a fellow of and lecturer in the Royal College of Physicians, and a member of the medical staff of St. Bartholomew's Hospital in London.

So great and so well recognised has been the influence of Harvey's work on the subsequent development of biological science in general and of medical science in particular, that during the past few months tercentenary celebrations have been held on a magnificent scale by the leading scientific and academic bodies all over the civilized world, notably in England, France and America. In England, indeed, the celebrations arranged by the Royal College of Physicians with the co-operation of the universities of Oxford and of Cambridge were attended by distinguished representatives of nearly every country and state in the world, the delegates being received by His Majesty the King-Emperor, who laid emphasis in his address on the international character of science, which knows no boundaries of race or of nation.

The story of Harvey's life has been related many times of late and even the lay newspapers have devoted considerable space to biographical details. It is unnecessary therefore for me to do more than give a brief outline of Harvey's life.

Born at Folkestone, Kent, in 1578, Harvey received his earlier education at Canterbury Grammar School and subsequently proceeded to Cambridge, where he went into residence in Caius College. After taking his degree in Arts, Harvey proceeded to Padua in North Italy for the study of medicine, as the English universities in those days made provision for the granting of medical degrees, but not for the courses of instruction leading up to them.

At that time Padua was in the very hey-day of its prosperity and pupils flocked to it from all over Europe—a special attraction being the presence of Fabricius of Aquapendente, a worthy successor in the chair of anatomy to the celebrated Vesalius, the father of modern scientific anatomical study. After studying for five years at Padua Harvey returned to England, received the M.D. degree from the University of Cambridge, and subsequently settled in London where he obtained a lectureship in the Royal College of Physicians.

For many years Harvey laboured in London, practising his profession successfully, lecturing at the College and above all devoting his spare time to carrying out a prodigious number of experiments. After about ten years of carefully conducted experimentation on the bodies of men and upon those of many different species of animals, Harvey began to teach his revolutionary doctrines at the College in 1616, but it was not until 1628, when he was absolutely certain that he had eliminated all sources of error and had considered all the criticisms of his colleagues in the College, that he gave the world his masterpiece, commonly spoken of as *De Motu Cordis*.

After its publication he continued his experimental work which led to his producing a remarkable book on the generation of animals. In this book Harvey first formulated the now generally accepted doctrine of epigenesis or development of the body by a process of differentiation from a simple germ. That eminent zoologist, the late Professor Huxley, was of opinion that Harvey's work in this connexion was of even greater importance than his better known work on the circulation of the blood. Harvey died in 1657 in his eightieth year.

Having briefly outlined his career I now turn to his accomplishments. What do we mean exactly when we say that Harvey discovered the circulation of the blood?

Before Harvey's time all the facts later known by him concerning the structure of the heart and blood-vessels had already been discovered, and indeed more than one writer had stated his belief that blood passed from the right side of the heart through the lungs and thence to the left side of the heart, but no experimental proof of this had been offered. Although anatomists had managed to discover all the important facts concerning the structure of the heart and blood vessels their ideas with regard to how they worked were totally wrong. To anyone who knows of the very high standard of professional skill of Vesalius and Fabricius it is amazing that they remained in ignorance of these matters and a most important object lesson is to be drawn from this.

At that time and for many centuries before, medical thought and teaching were entirely dominated by the writings of one man—Galen of Pergamum, who had lived in the second century of the Christian era. The works of this man came to be regarded as canonical, criticism of the views contained in them was regarded as medical blasphemy, and even when some of the descriptions of the structure of the body contained in the books of Galen were shown by dissection to be inaccurate there was a strong tendency to ignore facts and to cling to the doctrines of the Master. According to Galen the blood, after concoction in the liver, flowed to and fro in the arteries and veins independently after the manner of the ebb and flow of the tides. He supposed that there was an important connexion between the right and left sides of the heart by means of invisible pores and that spirits of three kinds—natural, animal and vital—were added in different parts of the body.

Harvey broke away from the usual subservience to the views of Galen. His long series of physiological experiments were so admirably conducted and so clearly recorded that they may be said even now to be a perfect example of how biological research should be carried out. Harvey found that one, and only one, state of affairs could explain satisfactorily all his experimental results, namely that the heart must be the prime mover of the blood, that it must pump the same blood over and over again, that the blood leaving the right side of the heart must pass through the lungs into the left side of the heart, and that the blood which leaves the left side of the heart by way of the arteries must eventually find its way into the veins and come back to the right side of the heart once more, *having a motion as it were in a circle*.

Now consider that Harvey had no com-pound in his disposal, that he therefore

could not see the minute blood vessels which connect the ends of the arterial branchings to those of the veins, and when we dwell on the fact that at that time oxygen had not been discovered and that therefore respiration was a function unknown, we must marvel at the extremely high standard of excellence of Harvey's experiments and at his powers of reasoning which led him to his conclusions. No person claiming to have received an education in science should fail to read an English translation of Harvey's book; it can be read through in an evening. It records in a simple and easily understood fashion one of the first and most important attempts to wrest knowledge from nature by means of careful experiment. Using experimental data Harvey showed that the actual quantity of blood leaving the heart at each beat, at the velocity at which he computed it must attain, could only arise from blood flowing back from the veins into the heart from a common circulating stock—this observation constituting one of the first applications of the idea of measurement to a biological investigation.

Having, inevitably, no conception of the function of respiration Harvey was, of course, unable to give a correct explanation of the object of the passage of the blood through the lungs.

Now although the discovery of the circulation of the blood was of supreme importance to physiology and to medicine, standing, as it has been put, in the same relation to these sciences as did the discovery of the magnetic compass to the science of navigation, it does not constitute Harvey's chief claim to rank with Galileo, Darwin and Newton as an outstanding leader in the advancement of science. His claim rests rather upon the attitude which he adopted towards the writings and dicta of the recognised authorities of the time, on the experimental methods which he devised for the solution of the problems confronting him, and on the clear-headed inductive reasoning which led him to his conclusions.

My reason for making William Harvey the subject of this address is not only that it is incumbent on us to recall to our memories at this time one on whose work our science and art is founded, but also that I think that we can find in Harvey's writings and methods many points which are very applicable to the medical problems facing us in the Indian Empire to-day.

We have seen that for very many years before Harvey was born progress in knowledge of the working of the body was definitely hindered, nay, rendered wellnigh impossible, by undue reverence for the writings of men who, although hampered by inadequate means of investigation, had centuries before formulated doctrines with regard to bodily structure and function. Instead of discarding what could easily have been proved to be wrong, men shut their eyes to any newly discovered facts which did not fit in with the doctrines of the Ancients.

We have in the Indian Empire to-day an exactly parallel situation.

Many hundreds of years ago when the inhabitants of most of those parts of the world to which the majority of scientific investigators now belong were rude and illiterate savages, there were in India as in China and other parts of the Orient many distinguished thinkers and workers in medicine and surgery as in other departments of learning. In India medical historians look back with justifiable pride on such stalwarts as Susruta, Charaka and Vagbhata who, nearly two thousand years ago, had made considerable progress in medicine and surgery. These Indian workers, however, have shared the fate of Galen in the West, and exponents of national Indian medicine are now engaged in teaching and in basing their practice on the archaic physiological and pathological doctrines laid down in the original Sanscrit so many centuries ago, and in explaining away any glaring discrepancies between their own doctrines and modern scientific discoveries by finding new and hitherto unthought of meanings for old Sanscrit words.

The whole of the Ayurvedic system of medicine is founded on the Tri-Dosha pathology according to which all disease is the result of the disorder of one or more of the three attributes of living matter—wind, water and bile. Ayurvedists' conceptions of the nature of disease have not advanced during the past thousand years, although the claim is made that all modern scientific knowledge is to be found in ancient Sanscrit documents if only they could be translated properly. The ease with which exact Sanscrit equivalents are found for every new term introduced to cope with modern scientific advance, such as hormone, vitamin, sympathetic system and vagotonia, makes one wonder if similar equivalents cannot also be found for such terms as sparking plug, thermionic valve and cathode ray, to bolster up the claims for the omniscience of the ancient Hindus in every branch of human knowledge.

Like Harvey one would say *I do not think it right or proper to take from the Ancients any honour that is their due*, and I would be the last person to detract from the achievements of the Ancients who, with the limited means at their disposal, seem to have accomplished marvels.

At this point it is convenient for me to define "modern scientific medicine."

By "modern scientific medicine" I mean "the prevention, alleviation and, if possible, cure of disease by any means which can be demonstrated to be efficacious."

It is founded on anatomy and physiology, that is the scientific study of the structure and functions of the body; on pathology,—the study of abnormal structure and function; on pharmacology,—the study of the actions of drugs on the normal and abnormal body; and on psychology and psycho-pathology,—the study of the normal and abnormal mind.

Stress must be laid on the fact that much of our progress depends on the application of advances made in the two basic sciences—chemistry and physics. Help is gratefully received from any source whatsoever, many of the most important advances being made by men with qualifications in pure science only, and this line of advance becomes more important every year on account of the fact that science is becoming so highly specialised that it is impossible for any one man to do more than have a thorough knowledge of one small branch. Nor must we forget the important advances in therapeutics which have been made from time to time by rude and uncultured natives in all parts of the globe, two of the most important being the discovery of the efficacy of cinchona bark in malaria by the South American Indians and of the virtues of foxglove leaves by English rusties. If at any time an accepted theory proves to be incorrect it is discarded or modified and a better one is substituted, for the chief use of a theory is to provide a working explanation for a particular group of phenomena until a better and more accurate explanation can be found. Compare this state of affairs with medicine according to any of the numerous systems which have had their vogue—the Ayurvedic system, the Homoeopathic system, the Allopathic system—each based on a specific and unalterable doctrine—and pursuing an unaltered course throughout the years. Harvey, with his intimate acquaintance with the evil wrought by the doctrine of "Hands off the Ancients" was constrained to write in the introduction to *De Motu Cordis*; true philosophers who are only eager for truth and knowledge never regard themselves as already so thoroughly informed but that they welcome further information from whomsoever and from whencesoever it may come. Nor are they so narrow minded as to imagine any of the Arts or Sciences transmitted to us by the Ancients in such a state of forwardness or completeness that nothing is left for the ingenuity and industry of others. Neither do they pin their faith to others' precepts in such wise that they lose their liberty and cease to give credence to the conclusions of their proper senses. Neither do they swear such fealty to their mistress—Antiquity—that they openly and in sight of all desert

their friend Truth. Neither do they think it unworthy of them to change their opinion if truth and undoubted demonstration require them to do so: nor do they esteem it discreditable to desert error though sanctioned by the highest authority. Yet to-day in the Indian Empire we have large numbers of the intelligentsia demanding that particular systems of medicine should be developed and subsidised by government on historical, sentimental and political grounds.

One even finds among the ranks of the Ayurvedists men who have been trained in modern medicine and who give "the partition of Bengal," "The Amritsar shooting" or some other political episode as the reason for their defection. What would one think if one heard that an eminent Indian physicist had abandoned the atomic theory as a protest against diarchy, or that a well-known mathematician had denied that three is the square root of nine as a protest against high railway fares? These examples are ridiculous, but their exact counterpart in medical science is accepted as a necessary consequence of political unrest.

Here I must make it quite clear that there is a profound difference between "indigenous medicine" and "indigenous medicines."

It is more than a little unfortunate that the word medicine should be used in two entirely different senses: in the first place as a designation for the art and science of preserving and restoring health, and second to denote the drugs and other therapeutic substances used in that art and science.

One commonly hears persons who do not fully understand the distinction assert that the indigenous systems of medicine should be supported and encouraged because drugs derived from fruits and herbs growing in the country must be cheaper and probably more efficacious than those brought from abroad. It cannot be too fully recognised that modern medicine is only too willing to try and to employ any medicinal substance if efficacious, from whatsoever source it may be obtained; and for many years the most distant portions of the earth have been ransacked for any substance which may be of even the slightest therapeutic value; and although the tendency nowadays is to synthesise medicinal substances artificially in the laboratory the search still goes on. To assume then, as many persons do, that there is something incompatible between modern scientific medicine and the employment of efficacious indigenous remedies is just as wrong as is the assumption that the best remedies for the diseases prevalent in any particular country must necessarily be found growing from the soil of that land. We know and even Ayurvedists will, I think, admit that medicine was practically powerless to deal with three of the most deadly diseases of the East—malaria, amoebic dysentery, and kala-azar—until non-indigenous drugs were introduced by modern scientific practitioners. For the effectual treatment of malaria we must use one or more of the derivatives of cinchona bark obtained from a tree indigenous in Peru in South America, to which continent we are also indebted for ipecacuanha and its potent derivative emetine. We can now save thousands annually in India and Assam from death from kala-azar—a disease with a recovery rate up to 1916 or so of almost nil—for with the new synthetic antimony compounds we are able to get a recovery rate of over 90 per cent.

A very different matter, however, from the employment of native remedies is the use of indigenous systems of medicine built up on a foundation of demonstrably wrong and non-progressive anatomy, physiology, and pathology, and owing its all to the dead and silent brains of long-gone ancient physicians. Nor does it seem to me to improve matters to lay down that in schools of Ayurveda and other indigenous systems modern anatomy and physiology should be taught in the earlier classes before the student passes on to learn the ancient system. To me it seems just as useless as it would be to institute a school of geocentric astronomy with the proviso that the first year

of the proposed course should be devoted to acquiring a sound knowledge of mathematics and physics.

"Doctrinaire formula worship—that is our real enemy" says Neuberger, and this is especially true when the health of the people of India seems to be in danger of being entrusted to devotees of antiquated, worn out and never changing cults. Let us in the Empire of India ever keep before us those words of Harvey which should be inscribed in letters of gold over the entrance to every teaching institution—*Search out and study the secrets of nature by way of experiment, and let us ever remember Harvey's words which we find in the introduction to The Generation of Animals. "Without the due admonition of the senses, without frequent observation and reiterated experiment our mind goes astray after phantoms and appearances. Diligent observation is therefore requisite in every science and the senses are to be frequently appealed to. We are, I say, to strive after personal experience—not to rely on the experience of others—without which, indeed, no one can properly become a student of any branch of natural science. I would not have you, gentle reader, to take anything on trust from me—I appeal to your own eyes as my witness and judge. The method of investigating truth commonly pursued at this time is to be held erroneous and almost foolish, in which so many enquire what others have said and omit to ask whether the things themselves be actually so or not."* Surely these words written three hundred years ago are highly applicable to conditions in India to-day.

From what I have said you will, I hope, readily understand why Harvey's name is revered in the world of science—not just because he was the discoverer of the circulation of the blood, nor because he was the first to introduce the idea of epigenesis into biology, but mainly because he set flame to the torch which lights the only safe path to the discovery of Truth in biological science—diligent and patient experimentation. Mark too how, no doubt partly as the result of the application of Harvey's own methods, the world of science has dealt with those portions of Harvey's works in which, in the light of later scientific discovery, such as those in oxidation, combustion and respiration, we now know that wrong conclusions were reached. These wrong views have been discarded without even a passing regret. How different from the fate of the mistaken views of Galen and of the earlier Indian physicians whose doctrines were and are still upheld on sentimental and political grounds. I say it would imply no disrespect for national heroes, no act of treachery or lack of patriotism on the part of the doctors of any particular nation to-day to abandon exploded theories instead of clinging to them on patriotic grounds.

Before concluding I should like to refer briefly to another aspect of Harvey's life—namely that of his attitude towards his brother physicians and fellow practitioners.

Towards even his most bitter opponents he maintained an attitude of courtesy. In his own words: *Ta return evil speaking with evil speaking I hold to be unworthy of a philosopher and of a searcher after truth. I believe I shall do better and more advisedly if I meet so many indications of ill breeding with the light of faithful and conclusive observation.*

Harvey was a generous man. He built at his own expense the museum and library of the Royal College of Physicians and handed over during his lifetime his patrimonial estate of Burmarsh in Kent, endowing also the annual feast on St. Luke's day, at which banquet the annual Harveian oration is delivered.

Harvey stipulated that in this oration the speaker should exhort the Fellows and Members of the said college not only to search out and study the secrets of nature by way of experiment but also for the honour of the profession to continue in mutual love and affection among themselves, ever remembering that *Concordia res parva crescent, discordia magna*

dilabuntur... (By harmony even small things become great but discord brings even great things to ruin).

There is, I think, to-day a great need in the Indian Empire for the development of more "mutual love and affection" between medical men, and "for the honour of the profession" it is to be hoped that something of the Harveian spirit will spread throughout our ranks in India, as I can imagine nothing more derogatory to the dignity and honour of our noble profession than the bickering, snarling, and intriguing, which are rife to-day between government and non-government doctors, between the different grades of practitioners, and between the adherents of ancient and modern methods of treatment. Fortunately we in Burma are not yet seriously embroiled in these matters, but I am sorry to say that in some parts of India a bitter strife goes on. May it soon cease, in order that the true objects of the medical profession—the common good and the public weal—may be restored to their proper places in the forefront of our activities.

Tbc—Protective Vaccine with dead Tubercle Bacilli.

By H. LANGER.

Therapic der Gegenwart, 1928, November.

IN spite of all counter attacks, Langer is still of the opinion that immunity can be attained by means of dead tubercle bacilli. To prove this statement he has again conducted experiments on rabbits. The animals were given a dose of 5 mgs. of the protective vaccine. After an interval of 2½ months the animals were infected with 0.0005 mg. of tubercle bacilli by intravenous or subcutaneous injections. Amongst the group of animals which received intravenous injections of tubercle bacilli, the control animals died after an average of 30 days, whereas the animals which had received the protective vaccine lived for an average of 70 days. In the group of animals which were injected with tubercle bacilli subcutaneously, the control animals lived for 68 days, whereas those animals which had been given protective vaccine lived for 270 days, one even living as long as 435 days. It has been shown that Langer's vaccine is free from harm. Some authors have been able to protect those infants who come out of tuberculosis-infected homes from an injection of this disease, by means of Langer's vaccine.

The Medical and Surgical Dossier or Patient's Case-Sheet.

By SIR MAURICE ABBOT-ANDERSON, C.V.O.,
M.B., B.S., ETC.,
and

E. P. SCOTT, M.B., B.S., M.R.C.S., L.R.C.P.

(*The Practitioner*, November, 1928, p. 180.)

EVERY medical practitioner must often have experienced the difficulty of obtaining from patients an accurate history of their previous illnesses. This state of affairs is no doubt largely due to the fact that the physician or surgeon in charge of a case does not enlighten the patient sufficiently as to the trouble from which he is suffering. This information can quite easily be given, and in such a way that it can readily be understood by the average lay intelligence. If this were done, the general public would become still more emancipated, the patient would be saved considerable expense, and the physician a vast amount of time, to say nothing of the increased accuracy that would be achieved in diagnosis.

We have been forcibly struck by the ignorance which prevails amongst all classes of patients concerning their

previous illnesses, and also in respect of the details of the treatment they have received, including the nature of operative measures that have been performed. Another important factor is the delay frequently caused by the necessity for communicating with physicians and surgeons as to the medical history of patients formerly in their care.

It seems to us a most extraordinary feature of everyday life that people submit themselves to treatment and to surgical procedure without really taking anything but an apathetic interest in the diagnosis and treatment of their cases. The following instances actually came under our notice recently:—

Case No. 1.—We were asked to see a lady suffering from abdominal pain; she had a median abdominal incision, and marked tenderness in the right iliac fossa. Our diagnosis would have been chronic appendicitis, but we were informed that her appendix had been removed some years previously. In the course of examination later, an opaque meal revealed a large kinked appendix, which was removed. It was subsequently discovered that the earlier operation had been performed for removal of the right ovary, together with the right Fallopian tube.

Case No. 2.—We recently saw a lady with a scar 11 inches long extending from the epigastrium to the symphysis pubis. She was quite unable to give us any information whatsoever as to the operation which she had undergone; all we could extract from her was that she "thought she had gall-stones." We found out from the surgeon who had operated that a partial gastrectomy had been performed, and that the gall-bladder had been left severely alone.

Case No. 3.—A further instance was that of a lady with a large scar in the right lumbar region. Why she was operated on she did not know, but it had been done in India by a surgeon whose name she had forgotten and who, she thought, was now out of practice, or possibly dead.

Medical instances are too numerous to relate, as, for example, the patient who tells the doctor that he has had vaccines, but for what he does not know! It is all very difficult and irregular, but could so easily be rectified if, in the first place, the physician or surgeon would definitely explain his illness to the patient; and, secondly, if the patient would insist upon having some record of his illness—a record to which he surely has a right. We would therefore suggest, with great temerity, that a written report or statement might be given to a patient after any more or less serious illness or operation, which report could easily and readily be produced in case of future need.

While discussing this subject, would it not be an excellent thing if the lay public were encouraged to take a little more interest in their general health (excluding, of course, that minority who constantly consult doctors, and of whom we all have experience), and to submit themselves regularly for general examination? In America, we believe, this is a usual practice. It is the common experience of every medical man to see patients who wonder why they have been turned down by an insurance company on the ground of ill-health; possibly an examination reveals that the blood pressure is too high, that albumen or sugar is present in the urine, or that some other physical sign exists which apparently gives no inconvenience, but is the distant though definite signal of "rocks ahead."

We can foresee in the near future a state of affairs when every doctor will be compelled to give a written report to each patient, and when every patient will be provided with a medical "dossier," which he will keep in his own care—a procedure which would obviously be in the best interest of the patient.

This dossier will be produced voluntarily by the patient, when asked for by the doctor he consults. It will very greatly help the physician in his work, and will considerably aid in safeguarding patients against errors of diagnosis. Think, for instance, of the importance of recording the fact that a certain patient has a definite idiosyncrasy to some particular drug, or

that another is a subject of hæmophilia. Records of exanthemata and vaccination would also be valuable.

It is obvious that there are certain drawbacks. A patient might resent a record that he had been a sufferer in his youth from venereal disease, but this could be got over in one case by merely stating that the Wassermann reaction had been absent or present on such-and-such a date, and other conditions could be indicated by similar indirect methods. Mention of the fact that the patient had been attended for alcoholism would also naturally be resented, but in drawing up the case-sheet some such indication as C_2H_5O , could be used. It would probably not be in the best interests of the patient to mention the fact that he or she had been operated upon for malignant disease, but here again a subterfuge would have to be adopted.

We would suggest that the form of the case-sheet should be determined by a committee of leading physicians and surgeons, and that this committee should invite suggestions from the profession generally. The scheme should also be submitted to eminent laymen, and an opinion should be taken as to the legal responsibility of the medical man signing the dossier. This, in our opinion, should be a privileged document, and it should be made compulsory by law that every doctor attending a patient should ask to see the patient's case-sheet. If the patient did not possess one, it would then be the doctor's legal obligation to provide this, and to complete his signed report as indicated on that case-sheet.

In time these medical records would be of great value statistically, and might even be of considerable importance from a medico-legal point of view. The whole subject has a wide bearing, but there is no doubt that such a dossier would be invaluable to its possessor.

The Origin of Civilisation.

(*The Med. Press and Circular*, October 17, 1928.)

AMONG other interesting theories suggested by Professor Elliot Smith is that the determining cause of the origin of civilisation was the presence of an abundant crop of wild barley on the banks of the Upper Nile, leading to the permanent congregation there of the nomadic races who inhabited that portion of the globe. An assured food supply led to an increasing population, the storage of the surplus food against the emergencies of climate, the cultivation of the arts and crafts, and the invention of an alcoholic drink, to which was attributed in the primitive mind the power of prolonging life, and which thus became associated with the idea of immortality. The almost universal presence of this and other beliefs in the ancient civilisations is considered by Professor Elliot Smith to be strong evidence against the independent origins of civilisation in various regions of the earth, and leads him to postulate the diffusion of culture from one primitive foundation. According to the older view, it was supposed that the human mind would react in favourable circumstances to the same instincts, and thus lead to the evolution of independent foci of civilisation, and in the end arrive at conditions of life varying only in the degree of culture.

Treatment of Ascites by Novasurol and Ammonium Chloride.

By SIR JOHN F. H. BROADBENT, M.D., Oxf., F.R.C.P. (Lond.)

(*Lancet*, June 30, 1928, p. 1326.)

NOVASUROL is a double salt of sodium mercurichlorophenyl oxyacetate with diethylbarbituric acid, and contains 33.9 per cent. of mercury. It is soluble in water and can be given by intravenous or intramuscular injections. It may be given in doses up to 2 c.cm. intramuscularly at intervals of three to seven days. Its tolerance should first be tested by giving 0.5 c.cm. intramuscularly.

Ammonium chloride is given by the mouth in divided doses up to grs. 150 in the 24 hours. I have found that 1 c.cm. of novasurol, followed by grs. 120 of ammonium chloride daily, was efficacious in producing marked diuresis.

The treatment of ascites by repeated tappings or ordinary diuretics is admittedly unsatisfactory. The explanation of the remarkable results obtained by the administration of novasurol and ammonium chloride is not clear. Rowntree, in addition, restricted the intake of water and salt, but this does not appear to be essential. Keith and Whelan came to the conclusion that the action of these diuretics was not limited to the kidney, but that extrarenal factors play an important part, and it is obvious that the transference of the fluid from the peritoneal cavity or the tissues to the blood stream is the primary difficulty and is essential for a satisfactory result.

Dr. George Curtis, described some experiments he had made on rabbits with the diuretic euphyllin. He found that during diuresis electrolytes form the greater part of the solids excreted in the urine, and that the chlorides calculated as sodium chloride, predominate. The sodium chloride content of the blood also rises. He concluded that under the influence of the specific diuretics permeability changes are initiated in the tissues, resulting in a rapid passage of electrolytes, principally chlorides, into the blood stream from the tissues. These stimulate the kidney and pass into the urine in large amounts. He found that when diuresis did not occur the marked increase in chloride excretion did not take place.

Irradiated Ergosterol as a Wound Dressing.

(*From The Prescriber*, September, 1928, Vol. XXII, p. 299.)

C. J. BOND (*Brit. Med. Journ.*, 3rd March, 1928, p. 339-340), having had successful results from the use of cholesterol and paraffin as a wound dressing, and having noticed that the results were still better when ultraviolet rays were used in addition, was led to try irradiated ergosterol ("radiostol") in oil, diluted with liquid paraffin, and soaked in gauze. He found that such a dressing not only reduces infection and promotes healthy granulations, but also stimulates the ingrowth of epithelial cells from the margin, and so favours the healing process. Bond thinks that further research should be made in this direction, and he suggests certain lines along which such research might be made. In a further note (*Brit. Med. Journ.*, 14th April, 1928, p. 642), Bond describes experiments which tend to show that this action of irradiated ergosterol on wounds and granulating surfaces may be due to the peroxide or ozonide of ergosterol rather than to vitamin D.

Albuminuria and Glycosuria.*

By ADOLPHE ABRAHAM, O.B.E., M.D. (Cantab.).

(*The Medical Press*, November 28, 1928, p. 446.)

THERE cannot be one practitioner who at some period or other of his career has not found reason to regret the omission to perform the elementary tests for albumin and sugar in the urine; and he is fortunate indeed if the omission occurs on a relatively unimportant occasion. This examination is in fact a fundamental precaution, whatever the condition from which the patient is suffering or the complaint he advances: and although I make no pretence to advance any new information, and can only claim the attempt to provide a convenient summary, there is no need to apologise for the elementary character of my subject. This is logically considered under two heads: the identification of albumin or sugar in the urine; and, secondly, the significance of their presence.

* Post-Graduate Lecture delivered at Westminster Hospital, 18th September, 1928, in connection with the Fellowship of Medicine.

Albuminuria means the passage into the urine of protein that is coagulable on boiling. The protein substances that may be encountered are serum proteins—serum albumin and globulin; compound proteins, nucleo-albumin and mucins; and proteolytic products—albumoses.

The familiar tests which have successfully withstood the attempted introduction of others, perhaps more delicate and less equivocal, are the application of heat and the addition of nitric acid; or, as they are popularly termed, the coagulation and the nitric acid tests. A urine with turbidity due to urates becomes clear on being heated; a cloudy precipitate which may subsequently form will be due to earthy phosphates or to coagulated albumin. The former is at once dissolved by a few drops of acetic acid, the latter becomes denser. It is well to add a few drops of acetic acid to the urine before boiling to ensure sufficient acidity. This precaution is in itself a test, as a precipitate which forms with acetic acid in the cold, as it is termed, is identified as nucleo-protein, which may be mistaken for albumin, but is of no pathological significance. A final precaution is to recognise an unusual phenomenon, a precipitate which appears at a comparatively low temperature and disappears on further heating. This is the Bence Jones albumose, which is an accompaniment of multiple myelomata, and is also found in some cases of leukaemia. It may be said that the average onset of coagulation of albumin is 75°C.; the Bence Jones body begins to precipitate out at 50°C.; at 58°C. it is well developed; at 70°C. clearing has already begun, and on boiling, the liquid should again be nearly if not quite clear. It is a rare phenomenon, but it is peculiarly striking. I once identified it in a routine examination of a medical man, who believed himself to be in perfect health, and in whom three months later symptoms first appeared.

The nitric acid test is, in my opinion, less convenient. An excess of urates may be precipitated, and so may nucleo-protein. There are also other fallacies, e.g., precipitation of copaiba resin, if the patient is taking this drug, and urica itself may be precipitated as the nitrate.

As regards genuine albuminuria, the percentage is usually below one and rarely exceeds two. The actual loss to the body is therefore of little importance, and is easily replaced. It is the significance which is of consequence. It may at once be said that the presence of albumin is not necessarily pathological, still less is it an indication of diseased kidneys. It is convenient to speak of pathological and non-pathological albuminuria; the latter may conveniently, if perhaps unscientifically, be called "physiological."

Pathological albuminuria occurs in nephritis, in other diseases of the kidney, e.g., tuberculosis and new growth, in suppurative conditions of the lower urinary tract—cystitis, urethritis; in hæmorrhage from any part of the urinary tract; in damage to the renal epithelium by toxins, exogenous or autogenous—this category will naturally include a very large number of conditions, e.g., alcoholism, burns, diabetes, gout, lead, mercury and arsenic poisoning, syphilis, foetal products in pregnancy. Albuminuria occurs in many of the acute specific fevers, particularly scarlet, diphtheria, variola, erysipelas; also in pneumonia and typhoid, less so in influenza and measles. In certain nervous disorders, apoplexy and convulsions; in circulatory disturbances, whether due to heart or lung disease, or to pressure on or obstruction of the inferior vena cava; ascites, ovarian tumours or cysts may be mentioned in this category. It is clear that a variety of causes may be responsible for the albuminuria of pregnancy, pressure of the uterus on veins, excessive strain on the placental circulation, the direct action of foetal products on the kidneys, not to mention the possibility of contamination of the urine by small hæmorrhages or vaginal discharges.

It will be evident that the significance of albuminuria in any one of these numerous conditions will depend upon the recognition of the cause which is primarily responsible. In some instances a clinical examination

suffices, in others a microscopical examination revealing the presence of casts, blood-cells, pus, organisms, will indicate the line along which further investigation should extend. It is impossible to consider such a vast subject even superficially, nor for the present purpose is it necessary.

To turn now to the condition regarded as non-pathological albuminuria. Some idea of its uncertain ætiology is afforded by the extensive terminology attached to it—physiological, adolescent, intermittent, remittent, cyclical, postural, functional, alimentary, the albuminuria of exercise.

In many instances there is a high percentage of globulin or euglobulin, and precipitation by acetic acid in the cold may be produced. In some instances the albumin may be detected only at certain hours of the day, being usually absent during recumbency, to appear during the active hours of the day. It is associated, therefore, with the erect attitude and also with exercise. In some cases there is also a paroxysmal hæmoglobinuria. In some cases the albuminuria is induced by a cold bath, or even a surface chill. All kinds of explanations are forthcoming. That posture has a distinct effect is indubitable, and it appears that lordosis of the spine is of consequence, as this exerts its influence when the subject is erect. The left renal vein is then compressed between the spine and the aorta, and it has been shown on occasion that such albuminuria may be derived from the left kidney only. Such a mechanical effect may be partly responsible for the albuminuria of pregnancy.

But even if posture and corresponding circulatory disturbance play a more or less indispensable part in the production of albuminuria, there must be an appropriate condition of the blood plasma. The subject usually displays many manifestations of vaso-motor instability, and the albuminuria may often be checked by the administration of calcium lactate. Certainly it may be checked by no other means short of perpetual recumbency, and the chief importance is to recognise the innocence of the condition, and not to restrict the subject's activities or in any way to prejudice him. This circumstance acquires particular importance in relation to exercise. The albumin which so commonly results after exertion is now regarded as negligible. It is found to be invariable in oarsmen, and in boys after any form of exercise; in my experience it is less common in adults who indulge in track athletics. As casts and blood are sometimes found with albumin, it is, perhaps, going too far to include these circumstances as functional only, but any nephritis which results would appear to be of the most trivial and temporary character. There appears to be no evidence that a so-called alimentary albuminuria ever occurs as a leakage when an excess of protein, e.g., eggs, has been taken.

GLYCOSURIA.

That glycosuria is not diabetes is nowadays an elementary truism. Our eminent predecessors, notwithstanding the lack of assistance from blood-sugar estimations which are a comparatively recent introduction, realised the existence of several conditions in which glycosuria was a transitory and trivial phenomenon, and even of conditions in which sugar was excreted in comparatively large quantities, yet without the usual pathological accompaniments of diabetes mellitus. To the latter the term *diabetes insipidus* was sometimes applied, a term which has now been replaced by "renal glycosuria," as removing any suggestion of a real diabetic condition and introducing a renal possibility, a consideration to which I shall shortly return.

Dextrose (or glucose) is the important carbohydrate excreted. Its identification as a substance which reduces Fehling's solution permits confusion with other reducing substances which may also be found in urine, some of which are carbohydrates, such as lactose, lævulose, maltose, and pentose. Lactose may be found in the urine of pregnant or puerperal women, lævulose and maltose as rare metabolic disturbances, and pentose still more rare. Another substance which reduces

Fehling's solution is glycuronic acid, which may result from the administration of large doses of chloral hydrate. In addition, an imperfectly performed test may result in reduction from the presence of uric, hippuric, homogentisic and salicylic acids, of creatin, creatinin, xanthin, and other bodies of this composition. So far as the identification of glucose is concerned, the result of fermentation with yeast will exclude lactose and pentose, a rare product which may occur after the ingestion of certain fruits rich in arabinose, cherries, plums, and pears, and also spontaneously as a metabolic freak, particularly in Jews. Fermentation will also exclude the large variety of non-carbohydrate substances above enumerated. If any doubt still remains as to whether glucose or some other sugar is present, subsidiary tests may be employed, rotation of the plane of polarised light, or production of appropriate osazone crystals. But this is really within the realm of the laboratory worker and not of the clinician. As in general, reduction of Fehling's or Benedict's solution means glycosuria, it will be well to spend a few moments discussing the performance of these tests.

First of all, it should be remembered that glucose is present normally in urine to perhaps 0.01 per cent., that Fehling's test will detect 0.02 per cent., and Benedict's considerably less. The delicacy of the last-named is indeed an objection to its clinical application, although it is immune to fallacies. As a rule, a urine containing an appreciable quantity of sugar has a specific gravity above 1.025, but discovery of a lower specific gravity must not be interpreted as evidence that glycosuria is absent. It has been shown that 1 per cent. glucose may be present in a urine of specific gravity 1.007, and even 1.003. Another practical consideration is the advantage of employing a twenty-four hours' specimen for examination, since an isolated specimen may be free from an abnormality present only at certain times of the day.

If Fehling's solution is used, the two solutions should be kept separately and mixed only at the time of testing, as the mixed solution tends to become self-reducing. At the time of performing the test, equal parts are mixed and boiled, an equal quantity of urine is separately boiled and added, preferably a few drops at a time to gain some impression of the quantity of sugar present. Prolonged boiling with Fehling's solution of a urine containing uric acid or creatinin may lead to reduction which will not occur if the reagent and the urine are separately boiled and then mixed.

Benedict's solution requires exactness in use. Five c.c. of the reagent must be measured, and eight to ten drops of urine added. The mixture is boiled for two minutes. A green, yellow or red precipitate forms, according to the quantity of sugar present. An important advantage is that the other substances which reduce Fehling's solution give a negative result with Benedict's.

Fermentation by yeast has already been mentioned as a confirmatory test of the presence of sugar. It also affords a method of estimating the quantity. The rationale of the test is that owing to decomposition of the sugar the specific gravity falls; every degree of specific gravity lost represents one grain of sugar per ounce.

Now, admitting the existence of glycosuria, let us turn to the circumstances in which it occurs. In the majority of subjects, sugar appears in the urine as soon as the blood-sugar exceeds about 0.17 per cent., and if an opportunity is afforded to estimate the percentage of sugar in the blood, the comparative importance of glycosuria becomes known. For, on the one hand, we may find in an established diabetic that the blood-sugar is substantially above 0.17 per cent., and yet sugar does not appear in the urine, so that a dangerous degree of hyperglycæmia may be overlooked because glycosuria is not present. On the other hand, the opposite condition may be encountered when glycosuria occurs, although the blood-sugar never rises even to the normal maximum, 0.17 per cent. In this case some peculiar condition of the kidneys appears to be present, and the term leaky kidneys or renal glycosuria is

employed. In the days which preceded blood-sugar examinations, such cases were regarded as diabetes, and treated quite unnecessarily by restriction or deprivation of carbohydrate. Their innocence was identified clinically by astute observers, who expressed their opinion by employing the term *diabetes innocens*. It may be added that a combination of diabetes with renal glycosuria may occur, but rarely.

The occurrence of glycosuria in cerebral tumours, epilepsy and nervous disturbances generally is very familiar. Such cases are the clinical representatives of glycosuria resulting from puncture of the floor of the fourth ventricle; the action is upon the sympathetic nervous system through the adrenals, and explains the temporary glycosuria which may result from excitement and other emotional disturbances.

Intermittent glycosuria is not infrequent in gouty subjects, and especially those addicted to alcoholic excess. It is sometimes (though not often) present in Graves' disease, presumably from antagonism of the thyroid and pancreas. For a similar reason glycosuria may occur in acromegaly.

The association with boils and sepsis is familiar. In children, glycosuria sometimes occurs shortly after an attack of pertussis.

Apart from the question of blood-sugar estimations, glycosuria acquires special importance when associated with the presence of acetone, *B*-oxybutyric and diacetic acids in the urine, and particularly the last two, since acetone may occur in the urine in a large number of relatively innocent conditions. In diabetes, the percentage of sugar bears no relation to the amount of diacetic acid excreted, but the presence of sugar encourages the test for *B*-oxybutyric acid which, although it cannot in itself intrinsically produce coma, is an essential factor. It is not strictly true to say that one tests for *B*-oxybutyric acid, for direct identification of this acid is very difficult. But since it is always accompanied by diacetic acid, the test for the latter by the simple addition of ferric perchloride is sufficient. The only fallacy in this test is the close similarity afforded by a urine containing the decomposition products of salicylic acid, which will be present if one of the coal-tar products has been administered. The colour is rather different, but sufficiently like for confusion if the possibility is forgotten. Naturally, prolonged boiling in the case of diacetic acid, which is volatile, destroys the colour which persists in the other instance.

Silver Nitrate in the Eye of the Newborn.

(From *The Prescriber*, September, 1928, Vol. XXII, p. 299.)

J. G. F. HEAL (*Brit. Journ. Ophthalm.*, Jan., 1928, pp. 33-35), reports a case of ophthalmia neonatorum treated prophylactically with instillations of silver nitrate (1.5 per cent.) thrice daily. At least five instillations had been made before he was called in. The child had conjunctival hæmorrhage and steamy cornea on both sides; on one side the hæmorrhage was so persistent that chloroform had to be administered to enable the cautery to be applied to the bleeding points. Five weeks later the eyes were normal. The lesson to be learned from this is that silver nitrate should not be used as a prophylactic for the eye in a solution stronger than one per cent., and caution is needed when such solution is used more than once.

The Prevention and Treatment of Tuberculosis by an Immunizing Vaccine.

By NATHAN RAW, C.M.G., M.D., F.R.C.S., F.R.S.E.

(*The Practitioner*, September, 1928, Vol. CXXI, p. 149.)

THE medical practitioner is always deeply concerned when he is asked to undertake the treatment of a patient suffering from tuberculosis. He knows that, if the disease is not arrested in the early stages, it will progress with certainty to a fatal termination. In spite

of an enormous amount of research going on in all parts of the world, we have reluctantly to admit that we have not yet obtained a specific remedy which will effectively destroy all the tubercle bacilli in the body without serious risk to the patient. We must therefore rely on producing a sufficient immunity in the tissues to resist the attack of virulent tubercle bacilli. This immunity can be obtained:—

(1) By increasing the natural resistance by means of increased nutrition and sound hygienic conditions.

(2) By producing an artificial active immunity in the tissues to the tubercle bacillus. It is to the latter (the production of active immunity) that I wish to direct the attention of the profession.

In considering this problem it is vital to appreciate the exact method by which the bacilli gain entrance to the human body, and, above all, the various types of bacilli which may affect it. The three principal types are as follows:—

(1) *Typus humanus*.

(2) *Typus bovinus*.

(3) *Avian type*.

In 1903 I published a paper, the gist of which was that human and bovine tuberculosis were separate and distinct infections, producing a different set of symptoms in the human body, and that they were probably antagonistic to each other.

The human type produces the greatest and most serious amount of tuberculosis in the form of pulmonary disease, popularly called consumption; it also causes tuberculous laryngitis, secondary intestinal ulceration, and, in some cases, lupus.

The bovine type of bacillus is introduced into the body through the alimentary tract in the form of infected milk, cheese, butter and dairy products, the infection usually being in very early life.

The avian type affects chickens and birds, which, in their turn, affect pigs in large numbers. This type is not pathogenic to man, and so we may disregard it.

A child affected with bovine bacilli may develop tuberculous glands, usually in the neck, mesenteric disease, affections of bones and joints, meningitis and lupus. Fortunately, these bovine lesions, if treated in the early stages, tend to natural cure, and do not seriously affect the general health afterwards.

The important point I wish to make is that these bovine affections undoubtedly confer an immunity against the more serious lesions caused by the human type, and in my experience a child who has recovered from glands and other bovine lesions is not so susceptible to pulmonary tuberculosis, and *vice versa*.

The two infections will not live in the human body at the same time. It is on this principle that I advocate the production of an active immunity in the prevention and treatment of the disease.

It has generally been held by pathologists that before a person can be considered immune to an infectious disease, he must be able to resist a virulent dose of the living organisms of the disease itself. This may be true in the laboratory, but it does not apply in practice. It is not necessary to produce complete immunity, as a partial active immunity is all that is necessary in the treatment and prevention of an infection in its early stages. We have a good example of this in anti-typhoid inoculation and in anti-tetanic serum, the wonderful effects of which I observed in the War. The immunity conferred was sufficient to deal with an early infection, and so prevent its spread and development in the body. It is not necessary either to use living cultures, as killed cultures of typhoid and para-typhoid are quite adequate and successful. In most of the acute infectious diseases, one attack confers an immunity to the patients for the rest of his life. This is not so in dealing with tuberculosis.

A person who has had pulmonary tuberculosis is always liable to a recurrence, even twenty years after a complete arrest. This is not observed to the same extent in cases of bovine lesions, and patients who have recovered from glands, bone and joint lesions rarely have a recurrence and often live to old age. It is for this reason that in attempting to produce an active

immunity, we must use a vaccine prepared from killed cultures of the opposite strain.

For example, a case of pulmonary tuberculosis which is of the human type must be treated with a vaccine prepared from bovine bacilli, and *vice versa*.

Professor Calmette always uses a living bovine culture which has been attenuated to the extent of making the bacilli non-pathogenic. I personally never use living cultures, being quite satisfied in my results with killed bacilli.

Preparation of Vaccine.

The vaccine is prepared from cultures which have been continuously subcultured on glycerine-agar medium every month in my laboratory for the last 22 years. The present cultures are of the 262nd generation. This long process has deprived the cultures of their virulence and they are now so attenuated as to be quite non-pathogenic and non-tuberculinogenic to animals. The cultures are all sterilized by heat before the vaccine is made. Being deprived of its virulence and toxicity, the vaccine produces no reactions, and can be given in much larger doses and with perfect safety.

Immunity.

With the object of preventing tuberculosis in dairy cows and thereby reducing the surgical tuberculosis in children caused by infected milk, I have been engaged during the last five years in immunizing calves shortly after birth, by giving them two injections of vaccine from human bacilli. The first one week after birth, and the second one week later. This has been done by competent veterinary surgeons, and we have records of over 2,200 calves. The results are excellent, and the immunity is at least over two years and probably longer. I look forward with great confidence to this method of attack, as, in my opinion, if we can eradicate the disease from dairy cows, we will to a great extent eliminate surgical tuberculosis from children.

Treatment of Early Cases.

From a very large experience in the treatment of patients suffering from tuberculosis in its varying stages, I have used tuberculin in over 2,000 hospital cases. I attribute the generally unfavourable results to the fact that the tuberculin was obtained from virulent cultures of human bacilli. The reactions produced in some cases were disturbing, and probably due to overdosage. This is entirely obviated by using attenuated bovine cultures, which never produce reactions if given in correct and graduated doses.

In early infections, the vaccine seems to produce sufficient active immunity to enable the tissues to produce sufficient anti-body to deal with the infection, and, what is of greater importance, to limit the spread of disease in the organ affected. During the last five years I have very carefully observed several cases in hospital in which the lesion was confined to one apex of the lung, bacilli being present in the sputum in every case. In most of the cases the disease has remained localized and arrested, showing no tendency to progress, a course of twelve injections being given every six months. I hope to report the final results of these selected cases in *The Practitioner* at a later date. The protection of the community by some safe scientific method of active immunization is the only effective way in which this preventable scourge can be eradicated.

The medical profession has, during the last few years, been losing their confidence in the specific treatment of tuberculosis by the various preparations of tuberculin. This can be accounted for by the fact that many of the tuberculins were prepared from virulent cultures which caused serious reactions and undoubtedly irritated the focus of infection. In my own experience it is not necessary to produce a reaction in the form of high temperature to achieve immunity. The vaccine should be prepared from cultures which have been deprived of their virulence and toxicity, and prepared from the opposite strains of tubercle bacilli. A case of pulmonary tuberculosis should be treated by a

vaccine prepared from bovine bacilli, and a case of surgical tuberculosis by a vaccine prepared from human bacilli. The dosage should be carefully graduated, and a course for treatment should consist of twelve weekly injections, the maximum dose being 0.01 mg. In no case are any reactions produced.

Reviews.

STUDIES ON MALARIA.—By Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S., F.R.C.S., Colonel, T.A. (Retd.), Major, I.M.S. (Retd.). London: John Murray, 1928. Pp. xi plus 196. Price, 5s. net.

As stated on the wrapper, "this book gives in a small compass all the essentials of the author's work on malaria from 1895 to the present time." Unfortunately, it also leaves out all the romantic details of the years 1897-1899, when the problem was finally solved. Anyone who wishes to follow the details of the research, the trials, the errors, the disappointments and official frustrations, through to the final crowning success, must search for such in the author's earlier *Memoirs*, of which the present work is really only a cheaper, abridged edition. Those who are particularly interested in malaria will naturally possess the larger work, those whose interest is less acute, or who merely wish to know how the thing was done, will, it is feared, turn from the present work with very little comprehension of how the discovery was really made, or of what it consisted.

Inevitably, after the actual account of the discovery, there follows the author's version of his controversy with the Italians over the question of priority. Long since settled in the author's favour, twenty-three out of one hundred and seventy-seven pages are devoted to an account of it from which no unprejudiced reader, or one approaching the subject for the first time, could possibly form a judgment, as, unlike the *Memoirs*, the text of the documents on either side is not quoted to any appreciable extent. Interspersed, however, with the actual account, are certain criticisms of Prof. Grassi's work which appear untenable. On page 22, Grassi's method of attempting to incriminate the carrier by "comparing the frequency of the different species in malarious and non-malarious areas" is stated to be one "which no sound scientific worker would have employed." We would ask why? It was admittedly not Ross' method, which would in any case have to have been used for the final proof, but it certainly served to "get a line" on the carrier. It is the method, moreover, by which suspicion was finally fastened on the sand-fly in the transmission of kala-azar. On page 24 the author doubts the possibility of new evidence coming to light in twenty-four hours. We would remind him that it was his dissection findings of 20th August, 1897, not before, not after, which will rank ultimately as a red-letter day in the history of the world. On page 39 he stigmatizes the Italians' first cultivation of quartan and benign tertian as "lucky experiments." This tallies ill with the "Angel of Fate" which led his own mosquito coolies, after unwittingly misleading him for years with Culicine mosquitoes to bring him Anopheles larvæ for the first time five days before his great date. Again, the fact that at Sierra Leone, a year later (page 43), the author discovered zygotes in one out of five *A. funestus* dissected on 13th August, will be held by everyone who has done dissections for parasites as surely a stroke of luck as anything that could have happened to the Italians.

On page 62, Giles' *Gnats or Mosquitoes* is unfavourably compared with Theobald's *Monograph*. Anyone who has had much to do with the systematics of the subject will surely ask why? On page 66, Manson's experiment in bringing infected mosquitoes from the Campagna and by them causing infection in London is animadverted on. Again, why? It is as capable of

repetition as any experiment of Ross', is far more spectacular, and was designed to convince a generally sceptical profession, not a few expert parasitologists.

On page 76, the author comments on a letter in the *Indian Medical Gazette* from Capt. S. P. James, concerning anophelines in rice-fields in Travancore. The same incident is referred to on page 427 of the *Memoirs*. In neither case is the text, or any part thereof of James' letter quoted. It seems useful to exhume this letter, which appears to have adversely affected the course of malaria prevention in India, from the files of the *Indian Medical Gazette*, as it apparently contains the earliest views of one who is now one of the foremost malariologists of the World.

"To the Editor of 'THE INDIAN MEDICAL GAZETTE.'"

SIR,—It is, I believe, generally considered that the breeding grounds of the malaria-carrying species of mosquito (viz., those with spotted wings) are few and far between. Major Ross has written with regard to the practicability of exterminating this variety of mosquito: 'The breeding grounds of the spotted-winged varieties seem to be so small and isolated that I think it may be possible to exterminate this species under certain circumstances.' He further states that in the cantonment of Secunderabad he was able to find the larvæ of spotted-winged mosquitoes only after a long search, in a single little pool which could be filled up with a few cartloads of town rubbish.

It would be fortunate if this were the case in all places where malaria is prevalent, but it is an important, though—from the point of view of their extermination—an unpleasant fact that in some places in India where malaria is exceedingly rife this 'dangerous' species of mosquito chooses for its breeding ground rice-fields near habitations, and large areas of water which from their nature are difficult to drain or remove. Such at least is the case in parts of Travancore.

On first coming to Quilon I searched for the spotted-winged varieties of mosquitoes in out-of-the-way pools and stagnant puddles of rain water away from habitations, neglecting the rice-fields which surround my bungalow on every side. For many weeks I was not able to obtain any of their larvæ and was the more surprised at this, as I was frequently able to catch spotted-winged mosquitoes in my bungalow, which had settled themselves on the curtains and clothes hanging up in the rooms. After many fruitless searches in every pool near the cantonment, I at last turned to the rice-fields round the bungalow, which were then covered for the most part with water to a depth of three or four inches; and here I found the larvæ of the spotted-winged varieties of mosquito in profusion. Since then from these rice-fields and from other large areas of water in the cantonment I have frequently been able to obtain a supply of these mosquitoes when none could be got from any pool or small collection of water near.

This circumstance, that apparently in many parts of the country where malaria is most prevalent the 'dangerous' varieties of mosquitoes are found to breed in rice-fields and other large areas of water, must add considerably to the task of exterminating them from such localities, should such at any time be attempted.—Yours faithfully,

S. P. JAMES, CAPT., I.M.S.,
19th Regt. M. I., Quilon, S. India.

QUILON,
TRAVANCORE,
27th September, 1899."

As the letter stands, it is easy to comprehend how Capt. James' finding may have been seized upon by opponents to discredit the possibility of malaria control by mosquito eradication. At this period nothing was known specifically of the Indian anophelines, only *barbirostris* and *sinensis* had been described, neither of them from India, though of course they existed there. The second paragraph of the letter shows that the

writer was under the apprehension that there was only one species of "spotted-winged mosquito," unlike Ross, who had already distinguished two, the "brown," (? *stephensi*) and the "small" (? *culicifacies*). Ross had found that both his species carried malaria, therefore James must have imagined that every "spotted-winged" species could do so. Ross and Daniels had yet to encounter the "crux" of the non-carrying *rossi* in Calcutta, and work on the carrying capacity of individual species was yet in the womb of futurity, necessarily awaiting delivery by the systematic entomologists, of whom James himself was later to become one of the pioneers in the group. It is easy, at this distance, to criticize, but assuming James' familiarity with Ross' technique, he could have checked for himself whether the abundant rice-field anophelines that invaded his bungalow were carrying or not, which he does not seem to have attempted before writing his letter, and could thus have avoided giving a handle to opponents in high places, as well as making a discovery of first class importance, viz., that under certain circumstances "the spotted-winged species" did not carry, or, granted the beginning of the systematically discriminative eye that he later came to possess, that there were more than one species of them, for in rice-fields he must have encountered the *fuliginosus* group with their very noticeable white hind tarsi, the *sinensis* group with their quite different wing pattern and general facies, as well as, perhaps, the black-legged *myzomyias* with four costal spots familiar to Ross. Moreover, even so early, a line might have been got on what is still the greatest unsolved aspect of the Indian malaria problem, its connection, or otherwise, with rice-fields, some of which, we now know, under certain circumstances to be malariferous, though the generality of such are not. *Vis-à-vis* rice-fields, our present methods of control, Paris green notwithstanding, fail, and until we can deal with rice-field malaria, where it exists, we are not in a position to afford much help to the countless Indian villages, and, as the reviewer has pointed out in a previous article, also reviewing a paper of Sir Ronald's, the benefits of malaria control are only enjoyed, or enjoyable, by Indians in the employ of capitalistic undertakings.

We can thoroughly sympathise with Sir Ronald over the incident recorded on page 106. In his case influenza, in our own bronchitis, has been misconstrued into malaria by persons anxious to disparage our work; though why there should be anything more for adverse comment in a malariologist's contracting the disease he is investigating than in a soldier in the front line getting wounded, we fail to comprehend!

The account of the Jenner Institute incident given in the present volume is even less clear than that given in the *Memoirs*, and we consider that unless the author is prepared to amplify the story, and quote Lord Lister's letter (which he evidently is not), the matter should have been left in oblivion. Surely anyone is entitled to change a post for a better one without other than financial reasons.

On page 134, the author strikes at the root of the whole trouble of the average malariologist, he is "only invited to advise, not to manage the work." How many of us have again and again conducted surveys and produced schemes, only to see them pigeon-holed, whilst the disease, the sickness and the loss continue. And one is then asked "what are you doing"?

On pages 151 and 152, the author refers to a most contentious article from his pen which has appeared even later than the book under review. An article which, if not controverted, may lead to results which we are certain he did not foresee, or desire. May we refer him back from page 152 to pages 12, 77, 116, and on to pages 164 and 171, of his volume? In the third reference we find him carrying out, in respect of his most successful practical campaign, the identical procedure for which he has in this article just held up his professional disciples to ridicule.

In chapter XX, the author deals with a subject which is barely mentioned in the *Memoirs*, and which

he styles "Pathometry." We may not agree with all he says in this chapter, notably his assumption that malaria has died out in England through reduction in the actual number of malaria-carrying Anophelines there, whilst we find it his excuse that England did not provide with material for improving his "conjectural constants" weak,—certain of them could assuredly have been experimentally evaluated as well, or even better, at home than in the tropics,—but we do consider that his energies would have been far more usefully devoted to collecting and collating his scattered papers on this subject into a "single small volume" than to producing the réchauffé which forms the subject of the present review. As a master of mathematics as well as malariology, he is fitted to deal with this vitally important matter in a way that few other malariologists are, and we would conclude by expressing the hope that Sir Ronald may be spared to give us in connected form the results of his investigations on this subject, results which we of the next generation can make use of in our daily struggle to continue his great work.

R. S. W.

UNE GRANDE PAGE DE L'HISTOIRE DE LA MÉDECINE: LA DÉCOUVERTE DE LA TRANSMISSION DU PALUDISME PAR LES MOUSTIQUES.

—By Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S., etc., preface and translation by Dr. Charles Broquet, Paris: Norbert Maloine. 1929. Pp. 173, with 9 plates and 7 figures. Price, 20 Francs.

THIS is the French translation of the author's Nobel Prize lecture of 1902, and we would at once say that it is by far the clearest and most interesting of the three accounts of his discovery published by Sir Ronald. Why, at a time when the original English article [*R. A. M. C. Journal*, April—June, 1905] was being reprinted in translation to form the present work, the author troubled to produce the condensation of his *Memoirs* which we reviewed above, passes our comprehension, for in the present work we have the whole research set forth with complete clarity, and can appreciate, as not even the *Memoirs* cause us to do, the various steps. From the restrained, though graphic eloquence of the translator's preface to the invaluable reproductions of the plates from the now unobtainable "Report on the Culture of *Proteosoma*, Labbe, in grey mosquitoes," and from figures in the articles in the *British Medical Journal* of 1897 and 1898, by Ross and Manson, the whole work has not a dull or unnecessary line. We are spared the tirades against the Italians, and have the case against them set forth briefly but succinctly. Of works easily obtainable, it is indubitably the most valuable account in existence.

There is little in the actual account that calls for comment, but we had not hitherto appreciated properly that the hypotheses of King and of Manson, taken conjointly, represented the actual truth, and that no one had done so is, we agree, "assez curieux," (p. 45). On page 64, we find the author himself pursuing, at Sigur Ghat, the epidemiological method for which he has blamed the Italians in his recent *Studies*, on which the reviewer passed detailed criticism in dealing with that work.

Of erroneous beliefs of the past there are a few still quoted, noticeably on pages 45 and 98, in connection with the life histories of *Piroplasma* and *Trypanosoma*, which might have been indicated by later-dated footnotes. The explanation of plate I does not indicate that figure 20 is that of "black spores," and not of a normal zygote of the sixth day. The date of the opening of the Calcutta Memorial Gate should be 7th January, not 17th. But these are minor blemishes. Far more serious is the very poor binding of the book. It is in paper covers, and our copy is already nearly disintegrated into individual leaves as the result of one through reading.

We as Britishers may very well feel proud that our French neighbours have sufficiently valued Sir Ronald's

work to publish, in a Medical Series, a detailed account of the discovery in their own language. Should any French admirer of Sir Ronald's work, however, come to Calcutta and visit the Ross Memorial Gate, he would be astonished at the dirty condition into which it has been allowed to pass. If, as a nation, we value our great investigators below the architectural magnificence which the French have risen to in the Pasteur Chapel, we can at least keep our less ambitious efforts in a reasonable state of preservation, the more so when their care devolves on members of the same great profession and service of which Sir Ronald is one of the first-magnitude luminaries.

R. S. W.

Note.—Since this was written, the Gate has been cleaned. We are sure that its present condition would entirely satisfy our reviewer.—Ed., I. M. G.

Annual Reports.

REPORT ON THE JAIL ADMINISTRATION OF THE PROVINCE OF ASSAM FOR THE YEAR 1927. BY COL. G. HUTCHESON, M.B., I.M.S., INSPECTOR-GENERAL OF PRISONS, ASSAM. PRINTED AT THE ASSAM SECRETARIAT PRINTING OFFICE, 1928. PRICE, Rs. 3-5.

Number of Jails.—There was no change in the number of jails and sub-jails during the year under report. The lock-ups at Hailakandi and Barpeta reverted to their former status as Magistrates' lock-ups from 1st September, 1927, and were no longer under the control of the Inspector-General of Prisons from that date.

Fluctuations in jail population (General Summary).—The year opened with a population of 2,331 prisoners of all classes against 2,257 in the previous year. The number of admissions increased by 1,000 and that of discharges by 1,047. The year closed with a population of 2,358 prisoners in jail, against 2,331 in 1926.

Number and disposal of convicts and proportion of the same to total population. (Statement No. I).—The year commenced with 1,928 convicts in confinement, of whom 1,905 were males and 23 females. The number imprisoned during the year was 3,597 males and 62 females against 3,240 males and 67 females in 1926. The total number of convicts dealt with during the year, including transfers from other jails both in and out of the province, was 7,357 against 6,719.

Distribution of convicts according to (a) Religion. (Statement No. II).—Of the total number of convicts admitted during the year 0.27 per cent. were Christians, 42.09 per cent. Muhammadans, 52.75 per cent. Hindus and Sikhs, .08 per cent. Buddhists and Jains and 4.81 per cent. all other classes.

Escapes. (Statement V).—As in the previous year, there were only 3 escapes against 7 in 1925. Of these two occurred at Silchar and one at Jorhat, all from outside the jails.

The total strength of permanent warders was 290, including 3 female warders at Sylhet, Gauhati and Tezpur, and 8 additional warders sanctioned during the year for the 4 sub-jails at Habiganj, Sunamganj, Karimganj and South-Sylhet.

In comparison with former years, the general health and mortality may be considered to have been very satisfactory.

The years 1924 and 1926, show the best records of the past ten years, and the figures for 1927 compare very favourably with them. Though the daily average population in 1927 was somewhat higher, the number of admissions to hospital and ratio per mille of admissions are lower than in 1924, and only slightly in excess

of 1926. The daily average sick 75.86 shows a slight increase over 74.29 in the previous year, while the ratio per mille was lower 31.32 against 31.02 in 1926.

The number of deaths in 1927 were 50, with a ratio per mille of 20.64, against 46 and 19.51, and 47 and 20.26 in 1924 and 1926, respectively, in which years the mortality was the lowest in the decennium. Sylhet alone showed 29 deaths, against 10 in 1924 and 18 in 1926, otherwise the record for the year would have been particularly good.

The ratio of deaths per mille was 20.64 in the jails of the province against the provincial death rate of 23.47.

The percentages of prisoners admitted in good, indifferent and bad health were 47, 45 and 8 against 51, 42 and 7, respectively, in the previous year. In the Assam Valley jails 32.58 per cent. were habitual drug-takers and in the Surma Valley 2.59 per cent.

There were no deaths in the district jails at Nowgong, Shillong, Kohima and Aijal or in the sub-jails at Sunamganj, Habiganj, South-Sylhet, Mangaldai, Sib-sagar, Golaghat and North Lakhimpur.

Sylhet.—This jail again shows an unfortunate mortality record. There were 29 deaths, all among convicts, with a ratio of 43.03 (district death rate being 26.21) against 18 and 25.08 in 1926, and 11 and 18.93 in 1925. The causes of death were pulmonary tuberculosis (10), tuberculosis of kidney (2), ankylostoma (2), pneumonia (2), enteritis (2), gastric ulcer (2), and enteric fever, leprosy, melancholia, meningeal hæmorrhage, thrombosis, meningitis, hepatic disease, malaria and scald, one each. Of these 29 convicts who died, 7 were admitted to jail in bad health, 15 in indifferent and 7 in good health. Twelve deaths occurred in November and December, and 6 of these were due to tubercular diseases. Eight deaths occurred within 4 months of admissions to jail, 3 being cases of tubercle. The 2 cases of ankylostoma were admitted to jail with general anasarca. Two cases died within 22 days of transfer from the Habiganj Sub-Jail.

The rise in the number of both admissions and deaths under tubercular diseases is remarkable and is difficult to explain. In this connection it is interesting to note that the number of patients treated for these diseases at the Sylhet Sadr Hospital rose from 76 in 1926 to 110 in 1927. The percentage of prisoners admitted in good health fell from 58.17 in 1925 to 50.28 in 1926 and to 45.14 in 1927.

The daily average sick rate fell from 32.01 in 1926 to 30.37, and the total number of admissions to hospital from 534 to 430.

For dysentery there were 26 admissions with no death in 1927 against 57 and 4 in the previous year.

Malaria showed a very marked decline from 73 admissions and 2 deaths in 1926 to 20 and 1 death in 1927.

Admissions for diarrhoea showed a very satisfactory fall from 69 to 8.

An epidemic of influenza occurred in July: there were 144 cases with no death.

The Sylhet Jail has the best hospital in the province and a competent medical staff. There has been no overcrowding in barracks and Lieut.-Colonel McCoy, assisted by his very experienced and reliable jailer and staff, has paid the minutest attention to every detail of the administration.

Jorhat.—There were 7 deaths with a ratio of 27.66 against 3 deaths and a ratio of 14.60 in the previous year. The deaths were due to tubercle of lungs (2), pneumonia (2), dysentery (2) and kala-azar (1). Two of these cases were admitted to jail in bad and 3 in indifferent health. One case of dysentery and one of advanced kala-azar were seriously ill on admission and remained in hospital till they died shortly after.

Gauhati.—Showed 4 deaths with a death rate of 10.26 which appears to be the lowest figure ever recorded in this jail. The Tezpur figures, viz., 3 deaths with a death rate of 9.22 are also extremely satisfactory and by far the lowest in the last ten years. The 2 deaths at Dibrugarh were due to causes outside the jail control, one patient being admitted suffering from

old standing tuberculosis and the other from enteric fever. At Dhubri there was 1 death from *kala-azar* against 4 in the previous year while Silchar showed one death from enteritis.

Subsidiary jails.—There were 3 deaths with a ratio of 10.10 against 1 death with a ratio of 3.58 per mille in the previous year.

The 2 deaths at Tura were due to dysentery and the one at Karimganj to chronic nephritis.

Sickness and mortality among convicts. (*Statement XIV*).—The daily average number of convicted prisoners for the year was 2,012.72 against 1,929.32. The number admitted to hospital was 1,165 giving a daily average sick rate of 67.75 against 1,115 and 65.73 in the previous year. All of the 50 deaths were among this class of prisoners.

Repatriated Andamans prisoners.—Three prisoners were received from the Andamans; one was received in a very bad state of health and died within a fortnight of his arrival. The health of the others is gradually improving.

The jails are experiencing considerable difficulty in the matter of suitable and profitable industries, and in finding a market for their manufactures. Attempts have been made to compete with the outside market for orders for tea baskets, etc., used in tea gardens and railways, but without success. The question of revising the system of fixing the value of jail-made goods is under consideration, and it will probably be necessary to reduce the percentage of profit. Far more assistance could be obtained from Government Departments if they placed orders with the jails for their requirements.

Arrangements are now being made for special classes for the training of prisoners in carpentry, smithy and masonry at the Sylhet and Gauhati Jails. This will teach trades which will be useful to prisoners on release, and will enable jails to undertake departmental works without employing outside labour.

Religious instructors.—Both Hindu and Muhammadan religious instructors were appointed for the jails at Silchar, Sylhet, Gauhati, Tezpur, Jorhat and Dibrugarh.

Discharged prisoners' aid societies.—There has been no response to the appeals made by Government in previous years to public-spirited persons to come forward to organise such societies.

Lunatics.—The same difficulties have been experienced as in previous years, but will disappear when the new Mental Hospital is completed. At Dibrugarh the number of lunatics has been usually 20 or more and they have been accommodated in the *hajal* ward.

Buildings.—The reconstruction of the Tezpur Jail commenced during the year and is making good progress. Major works completed or nearly completed include two workshops at Sylhet, a workshop at Jorhat, a wall round the Aijal Jail, and extension of the barrack and reconstruction of the workshop at Habiganj.

General.—Though there was an increase in population, the number of jail offences and of punishments was less than in 1926; the number of offences under "assaults and escapes" fell from 56 to 10, no corporal punishment was inflicted, and there were only 5 escapes (3 convicts and 2 undertrials), which is the same as in 1924 and the lowest figure for many years. The average remission earned by prisoners in days, and the number released under remission rules, increased, while the number who gained remission for special services rose from 171 in 1925 to 272 in 1926 and 339 in 1927. From these remarks it is evident that discipline has been well maintained.

With regard to health and in spite of the unfortunate record of Sylhet, the year under report compares very favourably with the best years 1924 and 1926 of the decennium.

Lieut.-Colonel H. Innes, I.M.S., was in charge of the Department from the 1st to the 31st January and Colonel G. Hutcheson, I.M.S., from the 1st February to the end of the year.

REPORT ON THE WORKING OF THE MENTAL HOSPITALS IN BURMA FOR THE YEAR 1927, BY COLONEL W. H. C. FORSTER, I.M.S., INSPECTOR-GENERAL OF CIVIL HOSPITALS, BURMA. SUPERINTENDENT, GOVERNMENT PRINTING AND STATIONERY, BURMA. PRICE, Re. 1-8.

The main features of the Burma Mental Hospitals report for 1927, are as follows:—

Accommodation.—The accommodation at the Mental Hospitals was for 1,821 (males 1,409, females 274) in Rangoon and males 138 at Minbu. There is accommodation for 275 sick in Rangoon (males 202, females 73) and this includes eight beds for males and eight for females for tubercular cases and 24 (12 males and 12 females) cells in which dysentery patients can be segregated.

At Tadagale, there is a contagious diseases ward which will accommodate eight patients. There was nowhere any overcrowding; but the five cells (brick walled and with cement flooring) for dangerous and noisy lunatics should be padded.

Population.—The population at St. John's Road Hospital, Rangoon, at the beginning of the year was 687 (549 males, 138 females).

At Tadagale, 186 males were accommodated.

The highest number confined on any single occasion was: Rangoon 624 (486 males, 138 females); Tadagale 324 males; Minbu 131 males.

The total average at the two Rangoon Hospitals was 922.80 (784.89 males, 137.91 females). At Minbu the average population was 129.75. During the year, 138 patients were transferred to Tadagale from Rangoon.

Admission.—There were 276 admissions during the year (this includes 19 re-admissions), 245 males, 31 females.

One hundred and thirty-four patients (113 males, 21 females) were discharged; of these 88 were reported cured; 33 improved; 13 otherwise.

In 1925, the number discharged cured was 80, in 1926, 71, and 1927, 88. Discharged improved were 28 in 1925; 30 in 1926; 33 in 1927. Friends or relatives will not come forward to accept the risk and trouble that is involved in caring for mental patients in their own homes.

Minbu Hospital admitted six observation cases, four were found to be insane, two were discharged.

Forty-seven per cent. of all admissions are from Rangoon and are usually of the cultivator class.

Seventy-five per cent. of all admitted are between 20 and 40 years of age.

During the year, 276 insanes were admitted to Rangoon Hospital—13 were due to hereditary predisposition, 37 had had previous attacks, 4 were in addition blind, 2 were cases of puerperal insanity and 19 were associated with a sudden mental stress, such as loss of property or near relations, 37 were associated with excessive indulgence in alcohol, whether as a cause or an associated symptom is not stated. In many of these cases, alcohol is probably the exciting cause, in otherwise predisposed subjects. Twenty-three were drug addicts. Opium, cocaine and cannabis indica are all noted as associated factors. Acquired syphilis is responsible for 10 male patients, the disease acting as an exciting cause resulting in impaired health and vascular degeneration. No ascertainable cause is assigned for 32 male patients; the information obtainable is scanty in most cases, but in certain cases nothing at all is known about past habits or family history. Considering the remarkable prevalence of venereal diseases in Rangoon, the proportion of cases of neuro-syphilis which results in mental failure is small, this is to be anticipated in a population largely engaged in manual labour. There were 32 cases of epilepsy, the pathology of which is unknown. There were 45 imbeciles, the imbecility probably due to congenital mental deficiency. Mania in a recurrent form greatly outweighs melancholia, but 45 cases of mania are shown as recovered sufficiently to enable them to be discharged. Eleven cases of mania and 7 of melancholia are associated

with old age. The admission of males is about 9 times that of females (271 males to 31 females). There are no doubt economic reasons for this. The actual proportion of male and female inmates to the general population is about equal, but as the men are more troublesome to look after they are sent to an asylum.

The general health was good. There was no epidemic during the year. There were, however, 77 cases of dysentery (72 of them men), of whom 8 died (elderly and infirm men). Eighty-nine per cent. of all cases recovered under treatment and careful nursing. All dysentery cases are segregated for two months after recovery.

There were 32 epileptics and 913 fits were observed and recorded, and 39 patients were artificially fed. All newly admitted cases were vaccinated. The whole population (including staff) were re-vaccinated during 1926. At Minbu, the general health was good throughout the year. There was no epidemic disease in the institution, though cholera and plague were prevalent outside in town and district.

There were 56 deaths (48 males and 8 females), and 9 cases for observation, brought in in a very weak state, died (7 males and 2 females); this compares with 57 deaths and 3 deaths (observation cases) in 1926.

The daily average sick was 42.20 in 1927; 29.08 in 1926; 77.70 in 1925. Percentage of deaths to average population 6.07 in 1927; 6.72 in 1926; 9.43 in 1925.

Dysentery, pulmonary tuberculosis, pneumonia, exhaustion from dementia and nephritis, accounted for most of the deaths.

Two deaths at Minbu were due to senility.

Escapes, Accidents, Suicides.—There were two escapes, one from Rangoon and one from Tadagale. The first was brought back from Shwabo by the Police after 18 days, and the second is still at large. The Eastern Subdivisional Magistrate held an enquiry into the cause of death in a demented case who died as the result of a chicken bone which lodged in his throat.

Sanitation.—The walls of all cells were scraped and treated with earth-oil. Wooden floors were treated with kerosine to dislodge bugs, where there was any reason to suspect their presence.

Tar and crude oil were issued for latrines. Jagged fly lotion containing sodium arsenite was freely used to destroy flies and has been most effective.

Dustbins are used for rubbish, and these and the latrines are regularly conserved.

At Tadagale, a waterborne sewage system is in use, thence sewage is carried through filtration beds to a sewage farm.

At Minbu, a dry earth system is in use; clean dry sand is used and the material removed three times.

Gardens and Dairy are both self-supporting, the vegetables produced supplied all requirements in the asylums and fetched by sales to staff and public Rs. 15,384-0-4. The value of the vegetables issued to patients was Rs. 14,462-4-4 and of those sold Rs. 921.

The cattle cost more to feed this year, for a large number of calves too young to sell could not be got rid of. Receipts from cattle were Rs. 6,868 and expenditure Rs. 5,672.

Diet.—There was no general change in diet. Variety within the sanctioned scale of expenditure was aimed at. Milk, soup and eggs were issued as extras. On festival days, a special diet of *palaw* and fruits was issued. Raw and cooked rations were examined daily and passed by the Deputy Superintendent.

Amusement and Recreation.—A gramophone is supplied to each section; *pwés* are occasionally held, and a band plays once a month during the dry season at the cost of the Corporation of Rangoon. Annual sports were held this year and successful competitors were given small money prizes. A special diet is issued on all these occasions as well as on special religious festivals. Various journals and newspapers were circulated with beneficial results.

Certain patients go under escort to churches, pagodas and bioscopes, and a few visit friends. *Chinlon*, football and badminton are played every day.

U Nyaneinda visited the Minbu Hospital on Sundays and festival days and preached to those who listen to him.

Employment.—The daily average employed on work at the Rangoon Hospital was 370 (males 341, females 29), at Tadagale 112. Labour is, however, not compulsory. Those able to do so and refusing to work were made to walk morning and evening as exercise. Money rewards varying from annas 2 to Re. 1-4-0, depending on the nature of work done, are given to encourage a useful and healthy occupation. Sweeping, cleaning of compounds, weeding, and jungle-cutting occupy the majority. Others assist in bathing helpless and demented patients, in distributing food, in washing clothes and cooking. The men in addition do carpentry, paddy-grinding, water-carrying and look after the asylum cattle. In Minbu, the inmates are employed in gardening, weaving, tailoring, paddy-grinding. The work was enough to maintain them in good condition. There was a daily issue of tobacco.

Cases, on admission, go to observation cells and a thorough and careful examination follows. Artificial feeding is used only in the last resort, when every effort to induce the patient to take food fails. Paraldehyde, sulphonal and trional were the most generally used drugs for treatment. A few cases needed hyoscine injections, where excitement was extreme. Strict personal hygiene and a suitable occupation were the chief factors in treatment. Water for drinking, for washing and the gardens is derived from wells in both hospitals. At Tadagale, 2 tube wells out of 4 borings have been in use. One failed, the 12 inches casing pipe having broken 200 feet below the surface, hence water consumption was reduced as far as possible. The fourth boring proved a failure and the Superintendent reports that the third well is not likely ever to work.

Bedding.—The patients made all their own clothing as well as the uniform of female keepers and servants. The change into khaki uniform necessitated purchase of materials during the year. The bed sheets used by different sections were differently coloured to distinguish them. A distinct dress was made for dysentery and itch cases. The patients, in addition, were given this year a bi-weekly change of clothing as a routine measure. Bedding was daily aired and exposed to sunlight when it was available. The arrangements for washing clothes and linen are on the whole satisfactory.

Weaving was the main industry in Rangoon and Minbu.

The average cost of each insane was Rs. 324 in 1927 against Rs. 318 in 1926.

It has recently been suggested that the full cost of maintenance shall be borne by the Local Authority sending the insane to the asylum; and Local Governments in India are being circularised with a view to ascertaining what the practice is there. On receipt of such information, as may be available, the question of the distribution of the cost of maintenance on a more equitable basis may well come up for consideration.

The Committee of Visitors met each month and three members selected in rotation to visit the hospital at Tadagale.

Staff.—Major H. A. H. Robson, I.M.S., was Superintendent throughout the year. Major E. A. Picachy, I.M.D., and Captain F. H. O'Leary, I.M.D., were Deputy Superintendents at St. John's Road and Tadagale, respectively.

Dr. K. R. Menon was in charge at the Minbu Mental Hospital.

REPORT ON THE STATISTICAL RETURNS OF THE PROVINCIAL MENTAL HOSPITAL IN ASSAM FOR THE YEAR 1927. BY COLONEL G. HUTCHESON, I.M.S. INSPECTOR-GENERAL OF CIVIL HOSPITALS, ASSAM. SHILLONG. PRINTED AT THE ASSAM GOVERNMENT PRESS, 1928. PRICE, 1s. 5d.

The main features of interest in the Report on the Statistical Returns of the Provincial Mental Hospital

in Assam for the year 1927, may briefly be summarised as follows:—

The total number of lunatics confined in the hospital at the end of the year was 437, of whom 352 were males and 85 females. During the year under report 63 (55 males and 8 females) were admitted into the Mental Hospital.

Three (2 males and 1 female and 2 criminal and 1 non-criminal) were re-admitted against 5 in 1926 and 7 in 1925. The intervals since discharge varied from 1 year 4 months to 6 years and 2 months.

The number of discharges excluding escapes and observation cases was 21 against 17 in 1926. Of these, all were discharged as "cured." The percentage of recoveries calculated on the daily average strength was 4.79 against 3.19 in the previous year.

There were 8 escapes (4 criminals and 4 non-criminals) against 5 in 1926; seven escaped from inside the palisade and 1 from the garden and all were re-captured.

The daily average strength was 438.47 against 438.38 in 1926.

No case was admitted for observation during the year.

On the 31st December, 1926, there were 214 criminal lunatics. Thirty were admitted and two re-admitted during the year; of these 246.9 were discharged and 23 died leaving 214 on the 31st December, 1927. The daily average strength was 213.39 against 212.12 in 1926.

Out of a total of 63 new admissions classified by religion, 48 were Hindus, 9 Muhammadans, 2 Indian Christians and 4 of other castes, 55 were males and 8 females. Of these 36 were natives of the province, 15 came from other provinces while the residences of the remaining 12 were unknown. In the province itself the districts of Sylhet and Cachar were responsible for the largest number of patients, viz., 14 and 7, respectively. Lakhimpur district actually sent the largest number of patients, but most of them belonged to provinces other than Assam.

As usual cultivators and tea-garden coolies furnished the largest number of admissions.

Between 20 and 40 years was the commonest age period.

The following types of insanity were admitted during the year:—

1. Mania	34
2. Melancholia	25
3. Insanity due to cannabis indica or its preparations or derivatives	5
4. Not yet diagnosed	2

Total (including 3 re-admissions) .. 66

Predisposing causes were known in 25, exciting causes in 20 and both causes in 20 cases. No cause was assignable in 38 cases.

The total number of admissions to hospital was 226 against 155 in 1926 with a daily average sick rate of 59.35 against 50.68 in the previous year. This excludes cases of epilepsy, the daily average of which was 34.90 against 35.40 in 1926.

The marked rise in the number of admissions to hospital is due chiefly to "dysentery" and "all other diseases." Under the latter head, 24 cases of cholera are included. The number of admissions for diarrhoea increased from 3 in 1926 to 17.

Only 4 patients were admitted for malaria, due largely to the regular prophylactic issue of cinchona febrifuge. Only one case of influenza occurred.

The figures for tuberculosis are the same as last year, viz., 11.

Dysentery was very prevalent, 102 patients being admitted against 39 in 1926. Most of the cases were "amoebic" in type. There were 23 deaths from this cause in a total mortality of 47 against 11 in a total of 33 in 1926.

Cholera broke out on 29th September and continued till 14th October, attacking 24 inmates and causing 9 deaths. The patients were all in the convalescent and

debilitated gang except one who was confined in a cell. This gang is fed separately near the hospital. No cases occurred in the healthy gang, or in female or tubercle enclosures, or in cells (except the case noted above). The Superintendent was unable to trace the exact origin of the outbreak, but it may have been due to a "carrier" or a new admission, as cholera was prevalent during the rains at every "ghat" on the river.

Under present conditions it is impossible to avoid the incidence of gastro-intestinal diseases from time to time, owing to the filthy habits of many of the inmates of a Mental Hospital and to overcrowding in the pueca barracks, which are limited in number. The temporary barracks remain more or less vacant as they are mostly unsafe and cannot therefore be utilised for patients who have dangerous propensities.

The percentage of new admissions in bad health was 13.64, indifferent health 54.54 and in good health 31.82, against 27.78, 53.70, 18.52, respectively, in 1926.

There were 47 deaths against 33 and 29 in previous years. The increase is due to the mortality from dysentery and cholera. Forty-one out of the total of 47 were due to dysentery 23, tuberculosis 9, and cholera 9. The figures for these diseases in 1926 were 11, 13, and nil, respectively.

Two patients died of pneumonia, one from an accidental injury to the spine, one from pyemic infection and the other two from cardiac and renal diseases.

The male inmates are employed on cultivation of vegetables, sugarcane and jute, manufacture of gur, repairs to buildings and palisading, carpentry, tailoring and usual daily routine duties. The females are employed on paddy husking, preparation of species, grinding of pulse for cattle food, cleaning, etc.

All inmates are encouraged as far as possible to play various games and those who are literate are provided with books, newspapers and pictorial magazines.

There was no addition to the accommodation for inmates during 1927. The accommodation available including cells, hospitals and tubercle wards, was for 356 males 85 females or a total of 441. The maximum number confined on any one night during the year was 443.

Filtered water is supplied from the Tezpur Water-works, but the supply is quite inadequate and it is necessary to supplement it from a well. The question of providing a separate pipe line for the Mental Hospital is under the consideration of Government and the Municipality. The food is good and sufficient. Extras are given to inmates in poor health and to tubercle cases.

Great care is taken in the matter of personal cleanliness, the daily bathing of all inmates and the regular washing and disinfection of beds, bedding and clothing.

Night-soil is regularly trenched in a selected site on hospital land outside the stockade and infected stools are incinerated.

The reconstruction scheme of the Mental Hospital has made considerable and very satisfactory progress. Rupees 1,96,680 has been spent on original works during 1927. The female section is nearly complete and will probably be handed over by the engineers in about 2 months. In the male section a number of barracks are being built and work will shortly commence on the main wall. The lay-out of the site is excellent, and every provision has been made for ample accommodation for patients in up-to-date barracks, hospitals, cells, etc., as well as for staff and mental quarters with room for expansion. When the project is completed in about 2 years, the Hospital will be able to accommodate 690 inmates, against 441 at the present time. This will satisfactorily solve all the difficulties in connection with overcrowding, and the segregation of new admissions and special diseases, as well as relieve the jails of providing for criminal and non-criminal lunatics for long periods.

There is a steady increase in the number of criminal lunatics who constitute more than half of the total male population, the daily average having risen from 187.98 to 213.39 during the last 7 years. When vacancies

occur the preference is given to criminal lunatics and then to most serious and chronic cases among non-criminals. Hence the percentage of recoveries to daily average strength is decreasing year by year.

All new admissions are vaccinated and treated with oil of chenopodium or carbon tetrachloride until found to be free from infection. Special attention is paid to cases of tubercle and pyorrhœa, and a prophylactic issue of cinchona febrifuge is given from May to October.

Lieut.-Colonel W. D. Ritchie, I.M.S., held charge of the Provincial Mental Hospital at Tezpur and Sub-Assistant Surgeon Mokhtar Hussain was the Deputy Superintendent throughout the year.

Correspondence.

THE ÆTIOLOGY OF NAGA SORE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In an original article published in the *Indian Medical Gazette*, December 1928, on the investigation into the ætiology and prevention of Naga sores in Assam, by D. N. Roy, M.B., D.T.M., the author lays stress on soil contamination as the probable cause of infection, but there are a few points which should be considered before arriving at this conclusion.

Since 1922 cement troughs containing a solution of phenyl have been gradually installed on all gardens in this practice, in which the majority of the coolies wash their feet twice daily on returning from work. These troughs are from 20 to 60 ft. long and are divided into two compartments, the first containing clean water, and the second a solution of phenyl which is deep enough to cover the lower third of the leg, the object of the first compartment is to cleanse the feet before proceeding into the disinfectant.

Each coolie on returning from plucking leaf has to walk through the trough in order to reach the weighing scales.

The result has been that cases of water sore, or *pani gao*, (for the prevention of which the troughs were intended), have decreased from the 1,612 in 1922 to 327 in 1928, which would tend to prove that the disinfecting solution was effective, but although it has proved effective in checking the number of cases of water sores, it has had no appreciable effect on Naga sores, and, if a batch of coolies were examined after returning from plucking or hoeing, it would be noticed that in very few instances was the soil adhering to the limb above the ankle but is often seen heavily coated on the feet, and yet the majority of the ulcers occur above the ankle.*

During the past year three Europeans were under treatment for Naga sores, one being a lady who avoids walking through the tea and the narrow paths in the garden, and is not particularly interested in her flower garden. The other two are tea house assistants, and their work is entirely indoor. In all of these cases the ulcers were well above the ankle. It has also been noticed that it is very seldom that any of the Indian staff are attacked although the Tellah babus have to walk through the tea in order to check the work, and as they do not wear trousers their legs are not protected. The only case that came under treatment was a Kerani babu who does office work only. Many coolies working in the tea house are affected, but in their case soil infection when going to the jungle in the early morning might be the cause.

In regard to the "eye-fly" being the transmitter of the disease, it is of interest that in 1927, there were

3,214 cases of Naga sores and ulcers recorded and 850 cases of ophthalmia, and in 1928, there were 1,800 cases of Naga sores and ulcers, and 1,126 cases of ophthalmia, so it would appear that the "eye-fly" is not the culprit; and yet the advent of the "eye-fly" and Naga sore are simultaneous.—Yours, etc.,

H. S. SMITH,
Medical Officer,
Baliserra Valley Estates.

KALIGHAT P. O.
SOUTH SYLHET, ASSAM.
The 1st February, 1929.

THE INTRAVENOUS USE OF PITUITRIN.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With regard to the correspondence in your columns in 1925, for and against the intravenous use of "pituitrin" and "infundin" in your issues for March, June and September of that year, I beg to crave publicity to report my own experience of the procedure in two cases of extreme emergency.

The first patient, an adult male, when first seen by me, was found to be in an advanced stage of collapse with an imperceptible pulse. There was not an instant to be lost. I administered straightaway 1 c.c. of undiluted "Hypoid Infundin" intravenously. The effect was magical; within a very few minutes what was apparently a dying man returned to life. Even I as a doctor was as amazed as the relatives to see the result. The case was one with very long-standing gonorrhœal complications, and death had appeared to be inevitable. Curiously enough, the injection proved to be the turning point in his illness, and from that moment the patient made a rapid and uneventful recovery.

Emboldened by this experience, I next tried the method in a case of pneumonia, an adult male, in whose facies at the time of crisis I read the signs of approaching death—a subnormal temperature with a run-away pulse, and a rapid dyspnoea with cold sweat on the forehead. At the instant when an intravenous dose of pituitrin was administered he stopped breathing, his eyes dimmed, and he appeared to have died, when suddenly he brightened up again, looked calm, felt comfortable, and the pulse and respiration became normal. He remained in a calm and comfortable condition for about thirty hours, when a second attack of heart failure carried him off before I could reach his house. This was a case of double pneumonia in a patient who was a confirmed drunkard and also the subject of untreated syphilis.

In neither case did I observe any of the train of symptoms mentioned by your correspondents, e.g., "sudden and intense pain in the chest and back, orthopnoea, paleness, and a terrified look," "colicky pains in the abdomen and pelvis."

With regard to the intravenous use of the drug in a diluted state, I have used it as a routine procedure in innumerable cases of cholera with the first pint of hypertonic saline, and always to my great satisfaction.

I am convinced that the intravenous use of pituitary extract should have a wide field of application in situations where no time is available for resort to other methods of injection. The question is to settle the best dilution that would be both safe and handy. It would help the general practitioner if either Messrs. Burroughs, Wellcome & Co. or Messrs. Parke, Davis & Co. would carry out the experiments necessary to determine this point, publish the results and place the prepared diluted solutions on the market.—Yours, etc.,

R. K. BHATTACHARYA, M.B.
NABADWIP, BENGAL.
25th January, 1929.

* *Manures*.—Practically the same kind of manures are used on all the gardens, and yet one garden may record many cases, and another in close proximity, and with similar soil may record but few cases.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Brevet-Colonel G. D. Franklin, C.I.E., O.B.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Residency Surgeon, Hyderabad, with effect from the 30th December, 1928.

Bt.-Colonel R. McCarrison, C.I.E., M.D., F.R.C.P., K.H.P., I.M.S., an officer of the Medical Research Department, is placed on foreign service under the Indian Research Fund Association, with effect from the 8th January, 1929.

Major J. Rodger, M.C., I.M.S., is appointed to officiate as an Agency Surgeon and is posted as Residency Surgeon, Mewar, with effect from the 7th January, 1929.

The services of Major P. D. Chopra, I.M.S., are placed permanently at the disposal of the Government of the Punjab, with effect from the 9th June, 1928 for employment in the Jail Department.

LEAVE.

Lieutenant-Colonel J. L. Lunham, I.M.S., is granted leave for six months with effect from the 30th April, 1929, or date of availing.

Lieutenant-Colonel H. M. H. Melhuish, D.S.O., I.M.S., Director of Public Health for the Government of Bombay, is granted leave for three months with effect from the 25th February, 1929, or the subsequent date or relief.

PROMOTIONS.

Majors to be Lieut.-Colonels.

A. J. Lee, M.B. Dated 30th January, 1929.

C. H. Smith, O.B.E., M.D., F.R.C.S., A. M. Dick, O.B.E., M.B., F.R.C.S., M. J. Holgate, O.B.E., M.B., T. L. Bomford, M.D., W. A. M. Jack, O.B.E., M.B., A. C. Anderson, K. S. Thakur, E. H. V. Hodge, M.B., G. T. Burke, M.B., M. A. Nicholson, M.B.—Dated 31st January, 1929.

Captains to be Majors.

D. Sanyal, M.B. Dated 5th January, 1929.

S. M. A. Faruki, M.D. Dated 6th January, 1929.

B. B. Gadgil, M.B. Dated 6th January, 1929.

Fazal-ud-Din, O.B.E. Dated 13th January, 1929.

P. N. Basu, M.B. Dated 16th January, 1929.

Haji Mohammad Salamat-Ullah, M.C., M.B. Dated 5th February, 1929.

R. Sen. Dated 7th February, 1929.

Lieutenant to be Captain.

V. A. Edge. Dated 16th December, 1928.

RESIGNATION.

Lieut. S. N. Evans. Dated 27th February, 1929.

NOTES.

VITAMINE THERAPY.

THE British Drug Houses, Ltd., are a well-known and most reliable firm of manufacturers, and their recently issued booklet on "Vitamin Therapy" will be of great interest to the medical profession in India. This booklet gives in summarised and illustrated form a resume of our present-day knowledge of the vitamins. It contains a brief outline of the whole question of the medicinal use of those vitamins which are lacking in natural foodstuffs; the occurrence and distribution of these vitamins in nature; their functions, processes of manufacture, and methods of standardisation. It also fully describes their vitamine preparations—Radiostol, Radiostoleum, and Radio-Malt. Finally, there is an interesting account of the standard to which their vitamin products are made to conform. The British

Drug Houses, Ltd., 16-30, Graham Street, City Road, London, N. 1. will be glad to send a copy of this booklet to any *bona fide* medical practitioner in this country who is interested in the subject. The pamphlet is very well got up and very well illustrated, and contains essential information for the general practitioner who has not had the leisure to absorb recent work on the value and use of the vitamins.

"SALVITÆ."

A most elegant preparation for use in conditions of gout, rheumatism, alimentary intoxication, migraine, nephritis, and acute inflammatory affections of the urogenital tract is "Salvitæ," prepared by the American Apothecaries Co. of New York. Its composition is stated to be as follows:

Strontii lactas	..	0.30	
Lithii carbonas	..	0.15	parts
Caffeine et Quinine			
Citras	..		0.80
Sodii-forma-benzoas	..	1.60	
Potassi et sodii citro-			
tartras	..		59.0

Sodii sulphas	..	30.0	per 100 parts.

It is obvious that such a formula is one especially adapted to combat acidosis, from whatever cause. It is antiseptic, depurant, diuretic, and anti-putrefactive. The dose suggested is from one to four teaspoonfuls dissolved in a glassful of water morning and evening.

In gout at least, the preparation has most soothing qualities, as we can testify from its use in a recent case. It is mildly aperient and of value in both specific and non-specific urethritis. It may be taken either in small doses as a diuretic, or, in larger doses as a mild saline aperient.

The Indian agents are as follows, and they will be glad to supply literature and samples of the preparation to the medical profession in this country:

Messrs. Muller, MacLean & Co., 8, Old Court House Street, Calcutta.

Messrs. Muller, MacLean & Co., 118, Gunbow Street, Fort, Bombay.

G. Y. Knight & Co., 71, Lewis Street, Rangoon.

Messrs. Wilson & Co., 5-8, Jehangier Street, Georgetown, Madras.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

"COOLY ITCH."

A PURULENT FOLLICULITIS DUE TO THE TRICHOPHYTON VIOLACEUM VARIETY INDICUM.

By HUGH W. ACTON,

LIEUTENANT-COLONEL, I.M.S.,

Director, Calcutta School of Tropical Medicine
and Hygiene,

and

C. MCGUIRE, D.T.M.,

Under the Indian Research Fund Association.

THE term "cooly itch" has been used to designate a type of pustular folliculitis affecting the lower classes (Indians), viz., coolies, etc., and is seen commonly on the thigh and legs. Unfortunately the use of this term has been extended to any form of purulent dermatitis, including scabies, because few attempts have been made to find the causative organism. Castellani employs the term "cooly itch" in a more restricted sense to an extremely irritative dermatitis that commonly attacks the lower classes, and is rarely seen amongst Europeans. He has not been able to find any causative agent, either fungi or insect parasite, and suggested that these lesions might be caused by some insect parasite that only remains on the body for a short time, analogous to the mite (*Tyroglyphus longior* Gervais) causing copra itch. As far back as 1922, the senior author recognised this chronic pustular folliculitis as a separate entity, and noticed that in men the pustules occurred round the hair follicles of the legs and thighs, and in women around the hair follicles of the forearm. Besides the pustules round the hair follicles, there was a good deal of perifollicular induration and inflammation, which gave rise to a peculiar purple coloration round each inflamed follicle. The disease is very intractable, and resists every form of local treatment by the ordinary parasitocidal remedies. The disease could only be cured by depilating the hairs in the area by x-ray exposures, showing that the causative agent grew along the hair shafts. At that time, we had not seriously undertaken any research on the subject, and we could only recover staphylococci and very rarely streptococci, in the few attempts made to isolate the causative organism. At first we considered the main cause of the chronicity and intractability of the lesions was due to the continual cross rub of the infected dhoti (loin cloth) or sari during the act of walking, etc. We could not advise our patients to change their clothes repeatedly as the majority of them only possessed a single loin cloth, nor to adopt any other method of dress, such as trousers.

The Indian Research Fund Association in 1925 gave a liberal grant in aid of these investigations which has enabled us to extend our researches into the causation of the different skin diseases met with in Calcutta. One of us (C. McG.) has devoted his whole time during the past three years to the study of the various cryptogamic fungi that invade the skin and hair follicles.

We soon discovered that this type of persistent pustular folliculitis was due to a *Trichophyton* closely resembling *T. violaceum* (Bodin), previously described and cultivated by numerous other workers. The *Trichophyton violaceum* attacks the hair of the scalp and beard and more rarely the glabrous skin and nails; the variety we have isolated attacks the hair follicles of the thigh, leg, forearm, front of the chest, beard and the back of the neck. So far we have not observed it to attack the scalp hairs except by extension from the beard area to the hair margin of the scalp and back of the neck. This variety of *Trichophyton violaceum* we proposed to consider as a subvariety and name it *indicum*. It differs from the *Trichophyton violaceum* (Bodin) in cultural appearances, but not in morphology; we consider the difference in cultural appearance not significant enough to enable us to describe it as a new species.

The clinical recognition of this type of ringworm folliculitis is extremely easy for any one who has seen a few cases of the disease, or has studied our water colour paintings. The demonstration of the fungi from the lesions by cultivation is, however, a very different matter, as it is difficult to isolate this fungus in pure culture. The difficulty is due to various causes, (1) the fungi are found in the more recent pustules and are not numerous on the hairs, so that selected pustules have to be examined. (2) The concomitant staphylococcal colonies, which are much faster in growth, overrun and strangle the fungal colonies. (3) The minute fungal colonies with their penetrating roots may be seen after the first days of insemination, but one is unable to subculture the fungi from these roots. (4) Any method we used to kill the staphylococcus generally succeeded in killing the trichophyton as well. Thus out of the cases diagnosed clinically we have only been able to obtain successful cultures in one out of every three or four cases, in spite of the fact that in most of the attempts we have seen submerged roots of the fungus invading the media.

During the course of this research we tested various chemical and physical means to inhibit the growth of the staphylococcal colonies, we found that gentian violet in 1 : 25,000 solution not only inhibited the staphylococcus but also killed the trichophyton. There is no doubt that, if every case of sycosis were carefully examined by a competent mycologist, the clinical entity would disappear from dermatological nomenclature and be regarded as a clinical manifestation of trichophyton ringworms. We found clinically that although the cases were refractory to the ordinary

parasitidal remedies such as chrysarobin, etc., they yielded readily to a solution of 1 : 20 gentian violet. There are certain objections to the treatment, the staining of the skin and clothes, but there is no doubt about its efficiency.

ÆTIOLOGY.

The disease is common amongst Indians of the lower classes in Calcutta, and is rare amongst Europeans. The few cases we have seen amongst the latter were mostly seafaring men, viz., officers of the mercantile marine, who are accustomed to walk about the decks in the early morning barefooted with their trousers tucked up above the knees. In Indians, the disease is seen largely amongst the cooly classes, and much more rarely amongst the middle and upper classes. The disease is more common amongst men than women; in men the lesions are seen round the hair follicles of the thighs and legs, and in women round the hairs on the forearm. Wrestlers are particularly liable to the disease, and hence the frequency amongst Indian policemen and *durvans* (gate keepers) who are keen wrestlers. In India the wrestling bouts take place on a small plot of land which is marked out and the earth well dug up to make the ground soft in order to lessen the impact of the throws. Preparatory to each bout, the combatants rub their bodies over with this soft earth to make themselves less greasy. During the contest, the whole of their bodies including the scalp gets well rubbed over with this earth. The fungus can live in the soil and thus gain an entrance into the hair follicle. In spite of this fact, only the hair follicles in the areas mentioned above get infected with this fungus.

There is little doubt that the cross rub of the clothes—*dhotie* and *sari*—that occurs during walking, etc., plays a very important part in the spread of the ringworm as well as in the secondary staphylococcal infection. The poorer classes can rarely afford more than a single garment be it a *dhotie* or *sari* to cover their bodies, and these clothes cannot usually be washed properly in soap and water. The dirty clothes tend to increase the incidence of the disease amongst them, and when once infected help to spread the disease from one hair follicle to the next. In a previous paper on *Tinea cruris*, Acton and McGuire (1927) showed the importance of moisture and friction in this common ringworm and how infection took place from the damp infected ground on to the thin glabrous skin of the feet. In this trichophyton infection, the source is again from the ground when the soil is dry and greasy, and the fungus only invades the hair follicle by prolonged contact in those who are not clean about their personal habits of bathing, etc. Dryness and friction from the clothes are important factors in the spread of this ringworm from one follicle to the other.

SIGNS AND SYMPTOMS.

The subjective symptom is intense irritation, causing the patients to scratch, in order to open

up the pustules or inflamed nodules and so relieve the inflammatory tension. The irritation becomes much more marked when the lesion has existed for some time and the induration has spread into the corium (*see* Plate IV, fig. 2). The typical lesion exhibits the following characters in the earliest stage when examined by a corneal lens of 10 magnifications. The hair shaft is surrounded by a tiny area of thickened epidermis, a greyish looking squame, which is not detached, and, where the epidermis is thinner, numerous fine dilated vessels are seen at the margin. Some of these areas go on to suppuration, a small pustule forming superficially round the entrance of the hair follicle so that the squame is lifted up and domed forming the upper boundary of the pustule; at first it is a greyish yellow colour and later on becomes a brighter yellow when pus has formed in it. The pustules are surrounded by a reddish purple zone of induration (inflammatory) which sometimes extends for some distance into the surrounding corium, producing nodular areas round each hair shaft. Many of these areas do not suppurate, and take a long time to break down. These reddish purple nodules round the hair follicles, some purulent and others not, are very characteristic of this ringworm infection (Plate I). In the beard area, the induration of the corium sometimes produces kerion, but on the legs the induration is more diffuse, so that the whole area of the skin becomes indurated and here and there pus points are seen round the hairs. At this stage, owing to the scratching and tearing of the skin, secondary infection by streptococci occurs; this only increases the induration (Plate IV, fig. 2) and changes the picture of the skin lesion to that of a weeping eczema (Plate IV, fig. 3).

The lesions are most commonly seen on the legs (Plate IV, fig. 1) starting on the outer side of the leg and extending along the hairs in this area. The induration extends into the corium (*see* Plate IV, fig. 2) and later may be followed by eczema (Plate IV, fig. 3). At other times it may start around the hairs of the thigh (*see* Plate IV, fig. 4), and in either case may become more widespread (Plate II), infecting almost every hair in the area. In women the lesions are more commonly seen on the extensor surface of the forearm (Plate III, fig. 1) where the hairs are more numerous and subjected to the cross rub of the *sari*. More rarely the hairs on the back of the hand (Plate III, fig. 3) may also be invaded by this fungus. The coarse hairs on the front of the chest are sometimes involved (Plate III, fig. 2) in an area which is frequently the site of acne as well, but the characteristic reddish purple colour of the nodules that have not as yet supplicated should prevent such a mistake being made by the physician. In men, the beard area is often attacked, giving rise to sycosis barbæ (Plate I), in this particular case as far as the temporal region. As a rule the scalp hairs are not attacked by the fungus, but the fine hairs on the back of the neck are sometimes invaded,

particularly those subjected to the cross rub of the collar or coat.

MYCOLOGY.

The first essential is to describe *the method of cultivation* adopted by us. An inflamed hair follicle is selected from the edge of the lesion and it is better to select discrete follicles, where the pus formation is beginning to occur round the hair shaft. It is impossible to get pure cultures either from large ripe pustules round the hair follicles or when a good deal of secondary infection with involvement of the corium has occurred in the centre of the lesion. The area is selected and the skin surface sterilised with absolute alcohol, each pustule is opened with a sterile needle, and a small loopful of the pus taken up and inseminated into three tubes of Sabouraud's maltose agar. In this manner the contents of six small pustules are sown on 18 culture tubes. In only one out of every four attempts are cultures successful for secondary implantation, as the more rapidly growing staphylococcus colonies overrun the more slowly growing fungal mycelium. In these infected cultures, even when the tube is broken and only the roots of the fungus that have invaded the media are taken up free of staphylococci, these root mycelia will not grow into colonies as in the allied cryptogamic fungi. When the colonies are separated from the staphylococcal colonies, secondary cultures can easily be made from the surface growth on most laboratory media at room temperature, i.e., 25—27°C. At present, we have not been able to evolve a method of cultivation such that we can hinder the growth of the staphylococci and allow the fungus to grow in pure culture. In most cases we are able to see the roots of the fungi penetrating the media, but less commonly, i.e., in only 1 in 4 cases, can we get pure subcultures.

Cultural characters.—On Sabouraud's test maltose agar (Plate V) at the end of the first week the colony is about 8 mm. in diameter, circular in shape, and raised above the surface level of the media. The centre of the raised area exhibits spicular projections into the air—aerial hyphæ. The colony is violet coloured, and when looked at from the side, thick dense roots are seen penetrating deeply into the agar media. After one month, the growth is 13 mm. long, ovoid in shape and very much raised above the surface of the agar, it has now a velvety mole-coloured appearance, very much like the colour and texture of the fine fur of this animal. The roots have penetrated through the media to the glass of the test tube, and are difficult to see, as the agar is pigmented a dark red brown to almost black colour. The growth on Sabouraud's maltose agar in an Erlenmeyer's flask after two months' growth is depicted in Plate V.

A description will be given of the appearances of the growth on the other media, seen after one month, incubated at room temperature between

25—27°C. On Sabouraud's glucose agar, the growth is 12 mm. long, ovoid in shape, raised above the surface, and has a velvety mole-coloured appearance; the medium is pigmented a dark red brown colour. On blood serum the growth is poor, only 3 mm. in diameter, the serum is liquefied and a small pit is formed, at the bottom of which is an area of growth. On peptone agar the growth is 5 mm. in diameter, raised above the surface, of a light mole colour, the media being pigmented a red brown colour. On potato the growth is 12 mm. in diameter, raised, brown in colour, but not velvety in appearance, the potato being dark in colour. On carrot the growth is 9 mm. in diameter, chocolate coloured, non-velvety in appearance, slightly raised; the edge of the growth is crenated and the surface rugose. On 2 per cent. glycerine agar, the growth is only 2 mm. in diameter. On 4 per cent. honey agar there is no growth.

The growth on synthetic media.—We next carried out an elaborate series of experiments to test the different constituents of the media in order to see what effect they would have on the growth of the different ringworm fungi. Our object was to devise a stable synthetic medium which would not hinder the growth of these fungi, but at the same time prevent pleomorphism. The objections to Sabouraud's media are two-fold, as he insisted that the peptone and glucose should be derived from two sources, viz., Chassaing's peptone and Chanut's glucose. Neither of these two substances are simple chemical compounds; however carefully the peptone is prepared it must vary slightly in its mixture of protein-like bodies, whilst Chanut's glucose cannot be obtained, so we have to use Merck's glucose, which under the best conditions is a very unstable sugar. We therefore considered it necessary to test the effect of varying the quantities of Sabouraud's test media, as regards its pH, the salt content and the amount of agar to see what effect these alterations would have on the growth of these fungi. It would be out of place to give the details of these experiments, but it is sufficient for our purpose to say that the best results obtained on these test media were given when the media contained 2.5 per cent. agar, the sodium chloride content 0.5 per cent. and the pH about 7. An alteration in the pH from 5 to 10 had very little effect on the growth of these different fungi. We next eliminated the peptone from the test media, and tried the different amino-acids to see how they would act as a substitute for peptone. We found the following combination of amino-acids to give the best results; arginine nitrate, sodium aspartate and tryptophane. We had now a synthetic media containing 2.5 per cent. agar, sodium chloride 0.5 per cent., pH of 7 and the above-mentioned amino-acid. The different sugars had to be tested. We found that saccharose was not only the most stable sugar but also the most suitable for our media. We were therefore able to devise finally a synthetic medium for our secondary cultures;

it is stable, and can be obtained in a chemically pure state, it does not materially inhibit the growth of these fungi and prevents pleomorphism. The fungi are able to live in this medium for at least two months. All our primary cultures are made on Sabouraud's medium, and the subcultures next tested on the synthetic medium, in order to prevent pleomorphism, etc. The composition of the medium is as follows:—

Argentine nitras	..	0.1 grms.	Mercks.
Tryptophane	..	0.05 grms.	Mercks.
Sodium aspartate	..	0.5 grms.	Mercks.
Saccharose	..	0.4 grms.	
Agar	..	2.5 grms.	
Sodii chlor.	..	0.5 grms.	
Water	..	100 c.c.	

pH 7.

The growth after one month on this media is depicted in Plate V. The size is 15 mm. in diameter, the central portion is raised, black in colour, 10 mm. in diameter, around the raised area is a depression and outside this depression is a flat orange-coloured growth with fine radiating furrows. The medium is slightly pigmented. As a comparison in the same plate (Plate V) the appearances of *Trichophyton violaceum* are shown on Sabouraud's test medium and on our synthetic medium.

MORPHOLOGY.

(Plate VII, fig. 4, photomicrograph, 2|3rd inch objective No. 10 ocular, shows how the roots of the mycelium penetrate into Sabouraud's maltose agar after one month's growth. The sections were made as follows. The glass tube containing the culture was broken and freehand sections were made across the agar media by means of a Gillette blade. These sections are allowed to dry, fixed, and then stained with weak carbol fuchsin. The mycelium is seen to consist of three parts. There are a few aerial hyphæ carrying the end organs of fructification, most of which have been lost during section, drying, etc. A very thick felted mass of surface runners or surface hyphæ by means of which the growth of the mycelium extends over the surface of the medium by a centripetal spread producing the round appearance of the ringworm. From these surface runners or hyphæ, deep roots penetrate into the media and sometimes go as far as the glass on the other side of the test tube. When viewed laterally, these root hyphæ form solid masses, particularly if the medium has been broken and air allowed to enter the crevice.

In Plate VIII, fig. 5, photomicrograph of these root hyphæ, 1|6th inch objective, No. 10 ocular, the older roots are seen to be segmented and the younger roots non-segmented and more uniform in their staining. We have tried various methods to obtain the exact picture of the relationship of the aerial hyphæ in sections in the downy and non-downy portions of the mycelium, but we have so far failed in our object. So we have to describe the appearances seen in hanging drop culture on Sabouraud's media. Plate VIII, fig. 6, is

a drawing made with an Abbe's camera lucida, the magnification being 1|6th inch objective and No. 10 ocular. A composite drawing gives a better idea than a photomicrograph as the aerial hyphæ are at different levels of focus. At the ends of the hyphæ are seen rounded uncoloured organs of reproduction, the chlamydospores. Along the hyphæ, thickenings of these elements will be seen as ovoid or rounded swellings, the intercalary chlamydospores. We have never observed any other variation in these aerial hyphæ except the two types of chlamydospores mentioned above.

In the pus taken from the recent pustules we have seen these end chlamydospores staining a deep purple with Manson's borax methylene blue and surrounded by a capsule.

Morbid Histology of the pustules.—Plate VI, fig. 1, photomicrograph taken with the 2|3rd inch objective and No. 10 ocular, is a section made through an infected hair follicle with early pustulation. The abscess is seen forming at the top of the hair follicle and only extending half way down the follicle so as not to affect the hair roots. Thus in this type of ringworm there is no baldness. Infiltration of the surrounding corium is taking place which later on gives rise to induration. Plate VI, fig. 2, photomicrograph, 1|6th inch objective and No. 10 ocular, gives a magnified view of the pustule which is situated at the top of the hair follicle; whilst Plate VII, fig. 3, is a photomicrograph made with the same magnification as given above in Fig. 2. The inflammatory process extends as far down as the top of the hair bulb, but the hair bulb is not affected by it so that the growth of hair is not interfered with in any way.

The schematic position of the fungus.—Many observers might consider this species to be a new one and different from *Trichophyton violaceum*. The essential differences would be that one species attacks the hairs of the head and beard, the other those of the beard and body. In one the mycelium is violet in colour and in the other it has a mole-like velvety appearance. Now the classification of these ringworm fungi is based on the morphological appearances as seen in hanging drop preparations after one or two months' culture. In both of these fungi we have the same type of organs of fructification, i.e., end chlamydospores and intercalary chlamydospores, so that they appear to be similar in morphological appearances. We have next to decide (1) are these differences in colour or (2) is the situation of growth sufficiently distinctive to create different species? We have always observed in our studies that coloration of these fungal colonies is largely a question of media. This is seen in Plate V. The European variety of *Trichophyton violaceum* loses all its colour on our synthetic medium; this may be perhaps due to continual laboratory cultivation; whilst our cultures become less mole-like in appearance and approach the Sabouraud's cultures of *Trichophyton violaceum*. The growth of the fungi on different parts of the body is largely a question of suitability of soil and not a

Cultures of *Trichophyton violaceum*. One month old cultures—reading from left to right. Variety *indicum*, on Sabouraud's maltose agar, synthetic media, and on an Erlenmayer's flask of maltose agar. those suggested by him. The technique is so extremely simple that if necessary a large number of tests can be carried out daily with very little trouble. The pipettes used are those supplied specifically for this test by the Bengal Scientific Supply Co. From the time of the transference of the blood and sodium citrate mixture to the pipettes, the readings are checked after 2 and 3 hours and an average of the two taken as the result.

Sedimentation rate—an indication of the amount of infection.

Patients suffering from uncomplicated nerve leprosy register an index of 10 to 20, which is similar to that found in healthy people. It is in skin leprosy, however, that the test is most useful, since by it we can gauge the amount of infection in the tissues apart from treatment, as well as check therapeutic changes. For example, if the lepra bacilli are few and difficult to find in large numbers in the skin, the sedimentation rate will be nearly normal, perhaps as low as 22. Again if they are plentiful, such as one finds in a nodulated skin, the sedimentation index may rise as high as 70 or 80, while between these extremes we get all sorts of variations. Also the case that registers say 28, previous to a dose of a reaction-producing drug like potassium iodide, may twelve hours after administration, register 33 or 35—thereby showing the effect of this drug. As clinical symptoms may or may not accompany this reaction, the change in the sedimentation rate of the blood corpuscles may be the only indication that a patient is reacting to potassium iodide at all.

As a guide to methods of treatment.

It is unwise to take anything for granted if one wishes to utilise potassium iodide in the treatment of leprosy. It is advisable therefore to take the sedimentation rate of every patient on admission and so avoid errors at the start. If previous to treatment the rate is low, say 20 to 28, we know that the resistance is good and that it will be safe to begin by using potassium iodide along with hydnocarpus preparations. In all probability the type of infection will not be acute and we can try to root out foci of the disease—always presupposing a careful and regular check on the sedimentation rate before and after the administration of potassium iodide.

Should the rate be high, 40 or more, resistance is poor and quite another method has to be followed. Most likely the lepra bacilli are accessible. Under such conditions a potent drug like potassium iodide would do a great deal of harm unless given in infinitesimal doses. A patient may look as if he could take 5 grains of potassium iodide and yet not be able to stand a fifth of that dosage. In such cases it is better to commence treatment with tonics and sodium hydnocarpate and afterwards, when resistance has developed, to give stronger preparations like iodide. But a good idea of the resistance of the

patient can often be gained by the blood sedimentation test. As resistance increases, the rate falls.

A knowledge, therefore, of the sedimentation rate enables us to sum up the severity of the infection in relation to the patient. It is sometimes a safer guide than even the bacteriological examination. If the latter is returned as negative and, after excluding complications, the rate is 28, we know that there are lepra bacilli in the tissues since, if they were absent, the rate would register between 10 and 20. If the sedimentation rate is high, say 47, and the patient has only a hyperpigmented area on his face with nose and skin positive, we know that he has a severe infection and treatment must be given carefully. Without such a guide as this test, it seems to me that it is difficult to decide correctly on methods of treatment in those cases.

As a guide during treatment.

It is well to test the sedimentation rate as often as possible during treatment, but it is specially useful to do so before and after the administration of potassium iodide, and so ascertain the non-reaction and reaction indices respectively. It is difficult to say which of these indices is the more important. At all events it is essential before each dose of potassium iodide to get back to the irreducible minimum of the non-reaction index. If this is not secured, the maximum resistance of the patient will not be resumed and one reaction will be grafted on top of another. This naturally brings difficulty in treatment as the patient's condition will be out of hand.

The clinical symptoms of a leprosy reaction, namely, temperature, erythema, rose-coloured nodules, etc., ought to disappear within two or three days from the time of their appearance. But this is no proof that the reaction itself come to an end. According to the sedimentation test it may continue after these symptoms have declined. For example, if the case complicated it may be a week before the rate to the patient's non-reaction index; and will maintain that he feels quite fit. With small experience of skin leprosy cognise how important such knowledge is out it, one sees patients becoming worse on iodide and severe types of the disease (infections) resulting.

Sometimes we have cases with a high sedimentation rate, say 40 to 50, in which the disease is very encysted in the tissues and difficult to reach. The lesions in such cases with a good deal of interstitial thickening, more or less erythematous. Such may be taking iodide till full doses are reached, but continue doing so for some weeks. Then they become "sensitized." If this sensitization is not detected by the sedimentation rate, it goes on to clinical symptoms of reaction, likely again to have a condition which is difficult to cope with.

The cases, however, which on the whole have benefited most by potassium iodide here, have been those which previously by oil treatment had had their resistance raised to the maximum.

Influence of hydnocarpus preparations on the sedimentation rate.

By the sedimentation test the hydnocarpus preparations reveal their two-fold therapeutic action, namely, that of autovaccination and their tonic effect. The former is shown by a rise in the sedimentation rate and may be accompanied by skin symptoms and temperature—all of which pass off in the usual way. It is almost needless to say that so long as this reaction is produced by the oil, it is hardly necessary to add potassium iodide to the treatment although, among the 120 cases dealt with in these notes, there is one patient who shows distinct idiosyncrasy to oil and takes potassium iodide very well.

As resistance increases this reaction effect of the oils passes off and their tonic effect only is manifested. At this stage the oil is a valuable agent in helping to bring down the sedimentation rate when it has been raised by iodide or by any other cause. It may require several doses to attain this, but the non-reaction index will ultimately be resumed—always excepting complicating factors which must be dealt with separately.

Other influence on the sedimentation rate.

Ble—present in the blood of 5 per cent. of these cases, so retarded the rate of sedimentation that the indices were lowered by 20 to 25 points. In such cases iodism may occur whereas ordinarily this is a condition about which few com-

plains. It accelerates the sedimentation rate raised by marked leucocytosis. A patient with a leprotic nerve only had a rate of 16. He was very wasted and in famine conditions. The same was noticed in a Brahmin patient who two years after he found he was suffering from leprosy.

When the sedimentation rate so much retarded by leucocytosis will leap up from 16 to 64 and continue high for some time after the leucocytosis has gone. When resistance is raised to a certain extent one can understand how it provides the conditions in which *M. lepra* can best flourish. In cases where resistance is already poor the malaria constitute a serious problem, and the temperature is allowed to remain high for any length of time.

Resistance and the sedimentation rate.

The sedimentation rate in leprosy when this is complicated by syphilis cannot be fully explained in these notes. As we know, syphilis increases resistance and is possibly one of the important factors in the etiology of leprosy. The use of mercury when administered by the mouth aggravates the disease and further raises

a sedimentation rate which is already high. This is especially so in skin cases who have had no treatment. Among those who have had specific anti-leprotic treatment as well as courses of Hg. 33 and N.A.B. one finds a certain percentage who benefit by mercury when given by the mouth. Among my 120 cases, in eighteen the Kahn test was highly positive. Two of these, who had just been admitted and had had no previous treatment of any kind, could not take mercury orally at all. Their leprosy flared up immediately. As to the others, the sedimentation rate was taken and mercury given orally to the point of mercurialism. This was treated and the patients left for 14 days, when the rate was again checked. In 10 there was no improvement evidenced by the sedimentation rate. In fact in some of them it had risen and when it fell later the former non-reaction index was maintained. The remaining 6, however, showed improvement. The rate had fallen in each.

Case A	previous to Hg.	S.R.	27	fell to	22
Case B	"	"	36	"	28.5
Case C	"	"	55	"	37
Case D	"	"	36	"	26
Case E	"	"	33	"	27.5
Case F	"	"	52	"	35.5

This would show that in syphilis complicating leprosy, one might give mercury by the mouth provided a close watch was kept on the sedimentation rate from day to day—deleting those patients who show a rise and pushing the dose in those who improve. No risks are run and the patients have a chance of receiving all possible help.

Conclusion.

From the above notes it should be evident that in the sedimentation test we have a means of controlling treatment hitherto unavailable; and we have learned that in anti-leprotic treatment there are limitations which this test reveals and which cannot be ignored. It repays one to study the relative resistance of each individual patient, and even if our treatment appears slow, on no account must this resistance be impinged upon.

NOTES FOR STAFF ENGAGED ON ANTI-MALARIAL WORK.

By W. D. SPEEDY, M.B., B.Ch. (T.C.D.),
Medical Officer, Raipur-Vizianagram Construction,
Bengal Nagpur Railway.

His experience of some twelve months as Medical Officer on the Raipur-Vizianagram Construction of the Bengal Nagpur Railway, has led the writer to publish these short notes, written for the benefit of his staff, in the hope that they may prove of help to others, who like himself are engaged on anti-malarial work.

He has been impressed more than ever by the havoc which malaria, uncontrolled by modern "protection" and medicine, makes with the inhabitants of a hyperendemic area, and feels that

no propaganda on the subject is wasted. The circular, a reproduction of which is seen below, has for this reason been distributed in addition to the Engineering Officers on the Construction, who have always given the greatest help and without whose co-operation the work would be impossible.

It is obviously desirable that the closest liaison between engineering and medical staffs be observed in the construction of important lines, more especially when these lead through country where malaria and other diseases exact a heavy toll from the labour employed. The medical man learns much from the engineer which is of practical value in this work, and is in turn able to assist the latter to avoid particularly deadly places when labour camps have to be selected, and it is hoped influences him to leave less of a legacy of malaria to the district in which he works.

No claim to originality is made. The system of "protected camps" is that devised by the malariologist of the line, R. Senior White, F.R.S.E., while the sketches accompanying the notes* are adapted from those issued at a very pleasant and instructive malaria class held at Saharanpur in October 1926, under Major G. Covell, M.D., I.M.S., of the Central Malaria Bureau.

Technical terms have been avoided as far as possible as the object of the notes is to provide an efficacious working minimum for the Assistant Malarial Inspectors or Sub-Assistant Surgeons employed who may have little or no special training when taking up the work.

In advising the weekly oiling of camps, the advice of an eminent orthopædic surgeon has been recalled. "Gentlemen, always overcorrect for deformities."

A somewhat egoistical reference to the railway to which I have the honour to belong, may be pardoned. Its inclusion has at heart the fostering of "esprit de corps" without which no unit, military or civil, may hope for any achievement worthy of note.

The "C. M. I." referred to in the text is the Chief Malarial Inspector, a trained man, whose duty it is to inspect and advise regarding the practical side of the work, cutting of drains, oiling, etc.

My thanks are due to J. A. Parker, B.Sc., A.M.I.C.E., District Engineer of Jeypore Plateau Survey, and Dr. A. Adhikari, my assistant, for helpful criticism.

Notes for Staff engaged on Anti-Malarial Work.

What is protection? It is a very definite and valuable kind of 'Preventive medical work.'

What is its value? It enables us to prevent malaria and other diseases carried by mosquitoes, by striking at these insects in their vulnerable stage.

It directly prevents much sickness, and in so doing saves for the Railway many hours and days which would otherwise be lost.

How is it carried out? Firstly by choosing camps in as healthy a place as possible, taking into consideration the work for which the camp is needed.

Secondly by preparing the ground in and around this camp within the half-mile radius so that all dangerous water is either drained away, or when this is not possible, treated with oil, etc., to render the breeding of mosquitoes impossible.

How does the mosquito grow? Starting life as an egg laid on the water, in favourable circumstances it hatches out as a larva in from two to four days. It lives as this 'wiggler' for a week or so before changing into a comma-shaped 'pupa,' from which within 24 to 48 hours the perfect insect emerges and flies away.

How does this life history affect your work? If the mosquito passes the pupal stage and gets on the wing, your work has been for nothing. It must be destroyed before it grows its wings, and remember that in various places this whole cycle may take place within a week, so that if you fail to treat every collection of water shown on your plan every seventh day, you are responsible for a flight of mosquitoes which may cause an outbreak of fever in the camp, for which you are responsible.

How will you protect a camp? 1. First walk all round it in gradually increasing circles from the centre until you reach the half-mile circle. Learn every inch of the ground. A small missed spring or collection of water may breed enough dangerous mosquitoes to wreck your whole work.

2. Your 'protection plan' will show as far as possible all dangerous places requiring treatment, but every camp is in a constant state of change as a result of rain, diversion of nullahs, etc., and you must use initiative in dealing with new breeding places. The C.M.I. will give you advice and directions on his inspections but always act at once. You will learn gradually the best measures to adopt in each case.

3. From 1 and 2 above you will have learned where mosquitoes are breeding, and your work is now to prevent this by drainage and treatment of water.

What types of water are dangerous?

Always.	Grassy edged streams.	Sometimes.
	Streams in ravines.	
	Hill foot seepages.	
	Running swamps.	
	Cracks and holes in black cotton soil.	
	Springs among rocks.	

Large streams and rivers may need treatment, and rice fields at times breed malarial mosquitoes but cannot be treated without special permission.

You will learn from the C.M.I. on the ground the best type of drain for each kind of water.

How will you treat water that cannot be drained?

1. In streams, pits, ravines, etc., by first having all grass, branches, leaves, etc., cleared from the edges and spraying with crude oil in which a small proportion of kerosine and cresol is generally mixed, or by fixing swabs soaked in oil upstream.

2. In ponds and standing water you will sometimes use cresol, mixed with the water in sufficient quantities to produce a milky tinge. (Do not use unless directed by the C.M.I.)

3. In swamps, paddy, etc., you will use Paris green mixed with dust.

How does oil kill larvæ and pupæ? By clogging up the breathing pores in the insect's body. If you leave grass, branches, etc., in the water you break the oil film and leave 'breathing holes' in the water, so that many larvæ, etc., escape destruction.

What about cresol? This is a definite poison and kills not only larvæ and pupæ but animals and man if used in sufficient strength; hence, the necessity for its careful use.

And Paris green? It is a form of arsenic, does not dissolve in the water but is swallowed by the larvæ only to whom it appears as food. It is useless for killing pupæ as they do not feed at this stage of their life.

Note.—Your work will chiefly consist in seeing that the coolies with whom you are provided do the cleaning and oiling work, every week without fail.

* Not published.—(EDITOR, I. M. G.).

If you have on occasions to get into a swamp, do so. Better men have been there before you.

Learn all you can about the work. Anti-malarial work is just beginning in India and vacancies will exist for men with experience in this Department.

The Bengal Nagpur Railway as usual is first away, and many other railways will follow.

Only men who are keen and conscientious are of any use in the Department. If you are not prepared to work to really stop malaria, you are not required.

A NOTE ON THE ANOPHELINE FAUNA OF A SMALL TANK THROUGHOUT THE YEAR.

By E. S. FEEGRADE,

Military Assistant Surgeon,

The Harcourt Butler Institute of Public Health,
Rangoon.

OBSERVATIONS on the tank immediately west of the Harcourt Butler Institute of Public Health for the determination of the species of anopheline mosquitoes breeding therein were spread over a period from January to December in 1927.

The tank is a small one, roughly about 50 yards square, with banks sloped at 45°,—well covered with grass and lined with large trees on all sides,—those on the west being close to the water's edge with overhanging branches which shade the water in the afternoon.

The character of the edges and surface of the water are different at different periods of the year. From January to May (practically the dry months of the year) the edges were free from grass encroachment and the surface was covered with red and green algæ which appeared late in January and gradually invaded the whole surface, thereby producing a mixed colouring of red and green. This growth moved about with the wind, leaving parts of the water-surface clear. At the onset of the monsoon in May the film thus formed by algæ broke up, and after a few showers disappeared entirely. Soon after the first fall of rain, grass invaded the edges of the tank and remained thus throughout the monsoon period and until the end of the year. Besides this grass invasion, three or four species of aquatic plants appeared and flourished concurrently providing suitable protection for the breeding of anopheline mosquitoes.

In the hot dry months of March and April, the water diminished considerably and a noticeable feature associated with this decrease was the abundance of prawns;—these crustaceæ are present throughout the year but not in such numbers as are found in the coldest and hottest seasons. Anopheline larvæ were not destroyed by these prawns experimentally and I assume that neither are they in nature. In addition to the presence of prawns, tadpoles and fish abounded, though the former existed in this form for only a short while before they metamorphosed into frogs; thus they were found in large numbers at the edges of the tank in the latter half of May, but

by June forsook the edges of the water for the grassy parts nearby. Prawns were found throughout the year and consisted of the following species:—

1. *Esonus ahli* Hora.
2. *Barbus punctatus sophore* (H. B.).
3. *Ctenogobius alcocki* (Annan).
4. *Macronectes gulo* (H. B.).

The first three species were collected in the deeper parts and the fourth near the edges. All four species were found to destroy larvæ under laboratory conditions.

The pH value of the water varied from 7.2 to 7.8. The alkalinity increased from January, rising gradually until 7.8 was recorded in May before the first heavy fall of rain. The pH value dropped to 7.2 with the first big fall of rain and alternated between 7.2 and 7.4 throughout the wet season, whereas a long interval without rain occasioned a higher alkalinity.

The anopheline fauna consisted of:—

- A. fuliginosus* Giles.
- A. hyrcanus* var. *nigerrimus* Giles.
- A. barbipennis* Van der Wulp.
- A. vagus* Donitz.

A. fuliginosus.—This is an interesting species, because of its reputation as a common carrier in the plains of Burma, and in this case it was found breeding in small numbers along the grassy edges of the tank in January. As the water decreased there was no corresponding grassy encroachment, and with the appearance of the red and green algæ, the larvæ of this species also had decreased considerably by the end of the month until none were obtainable. They were not seen again until early in June when they were collected in large numbers where grass and other aquatic plants were invading the edges and when the pH of the water fluctuated between 7.2 and 7.4. Throughout the wet season from June to October, and also from November to January they were found breeding in the tank,—the former period being that in which they were most prevalent.

A. hyrcanus var. *nigerrimus* and *A. barbipennis* bred in the same season as *A. fuliginosus*, but in much smaller numbers in the early and middle parts of the rains and in larger numbers at the end of the monsoon. These species decreased in January and later were not obtainable.

The finding of *A. vagus* in a tank is an unusual feature, but they were found on only a single occasion.

A. fuliginosus is a known transmitter of malaria both in India and Burma, in which latter country it is common, but although it bred in such large numbers it is an interesting fact that there was no evidence of its producing malaria in this neighbourhood. What are the reasons for this? The chief one is, I think, that they have not become infected by feeding on human carriers, for the majority of residents in the vicinity of the tank are more or less permanent inhabitants and have not been exposed

to infection by travelling in infected areas. It would be interesting to get this species experimentally infected to ascertain if they could transmit the disease to an uninfected individual. For if the parasite does not grow in the species of mosquito which breeds in this tank, well and good; but if they do—yet cannot transmit the parasite to man—it may throw some light on the fact that there are certain species which, although they transmit malaria in some places, do not do so in others, even though they feed on infected men.

In conclusion I wish to place on record that, during my absence in the rainy season, these observations were partly carried out by Sub-Assistant Surgeon, U. Tin, to whom I am indebted for his collaboration.

EXPERIMENTS WITH ISOTEX AS A LARVICIDE.

By E. S. FEEGRADE,

*Military Assistant Surgeon, The Harcourt Butler
Institute of Public Health, Rangoon.*

"ISOTEX," a proprietary preparation of the Chemical Company of New York, 49 Broadway, New York, is reputed to destroy pests which breed in and inhabit swamps, polluted pools, garbage, and waste dumps.

It is a dark brown fluid, forming a thick film on the surface of water, adheres to any surface, even glass, stains clothes, and is stated by the manufacturers to be poisonous.

Experiments were conducted with anophelines and culicines both in the laboratory at the Harcourt Butler Institute of Public Health and in their natural breeding-places.

The final conclusion of the laboratory experiments was that the minimum quantity of Isotex required to kill specimens of both subfamilies of larvæ within 1 hour was 1 c.c. spread on 3,000 c.c. of tap water with a surface area of $8\frac{1}{2}$ inches \times $3\frac{1}{2}$ inches and a depth of $6\frac{1}{2}$ inches, even though the film did not cover the entire surface of water.

Younger larvæ were killed off early, even within 5 minutes, but the mature ones within the time already stated. Larvæ, young and old alike, which came in contact with the solution when the latter was being poured onto the surface, died almost immediately.

Thereafter with the same apparatus and the same quantities of fluid as above, but with cut grass added to the surface of the water, the death of the larvæ was delayed to a maximum period of 75 minutes.

Under similar conditions fish of the species of *Haplochilus panchax*—a surface breeder—were killed in 10 to 15 minutes.

In experimenting in natural breeding-places, pools and drains were considered to be most suited for the purpose. The pools selected measured approximately 6 feet broad, 12 feet

long, and 2 feet deep at their deepest part. At the margins where it was 1 to 2 feet deep there was much aquatic vegetation, sheltering larvæ of anophelines, culicines, pond skaters, spiders, water beetles, and *Haplochilus panchax*. Here 30 c.c. of Isotex was the minimum quantity found to destroy all aquatic life in 75 minutes.

Experiments were next carried out in sections of a drain, 15 feet long, 5 feet wide, and $2\frac{1}{2}$ feet deep, with much aquatic growth along both edges, and with a clear space of about a foot in its middle. In this case larvæ and other aquatic fauna—such as were noted in the case of the pools—required 60 c.c. of Isotex to destroy them in 45 minutes as they were unable to escape because of the thick aquatic vegetation.

Isotex is a powerful larvicide, but it is also fatal to fish, and for this latter reason I do not consider it suitable for use in anti-malarial measures.

A SIMPLE METHOD FOR THE ESTIMATION OF BLOOD UREA APPLICABLE AT THE BEDSIDE.

By HARENDRA NATH MUKHERJEE, B.Sc., M.B.,
D.I.C. (Lond.),

*Biochemical Department, Carmichael Medical College,
Belgachia, Calcutta.*

Of the many biochemical tests done on the blood for clinical purposes, the estimation of blood urea is one of the most important. This is indicated in nephritis, uræmia, enlarged prostate, obstruction to the urinary flow, and various other conditions and throws considerable light on the condition of the patient. In normal healthy Bengalees it is rare to find a blood urea-nitrogen value greater than 14 mg. per 100 c.c. of the blood. In uræmia, and in other conditions with impaired kidney function, notably in cholera—it is greatly increased. Values as great as 100 mg. per 100 c.c. of blood may be met with in these conditions and indicate a very bad prognosis.

There are many excellent methods for the estimation of the blood urea, but as they require considerable laboratory facilities and apparatus, they are not suitable for patients in the remote mofussil. In the present paper a very simple method for estimating the blood urea is given which can be easily performed in the mofussil or even at the bedside. The results obtained are quite reliable for clinical purposes.

This method is based on the method of Fosse, Robyn and François (1914) by which urea is precipitated as dioxanthidryl urea by the addition of an alcoholic solution of xanthidryl. Nicloux and Welter (1921) found the xanthidryl method to be very reliable even with very small quantities of urea. Recently Beattie (1928) and also Luck (1928) independently have described methods for estimation of blood urea by means of xanthidryl. Beattie has estimated the dioxanthidryl urea formed colorimetrically by dissolving the

precipitate (after removal of the excess of xanthidrol by washing with methyl alcohol), in sulphuric acid (50 per cent. by volume) in which xanthidrol and its compounds dissolve producing an intense yellow colour. She has filtered off the precipitate of dioxanthidryl urea by suction through a Gooch crucible packed with asbestos. The precipitate was then thoroughly washed with methyl alcohol, preferably saturated with dioxanthidryl urea, and then dissolved in 50 per cent. sulphuric acid for colorimetric estimation against a standard.

Luck has utilized the property of dioxanthidryl urea to be readily oxidised as the basis of a quantitative method. The precipitate of dioxanthidryl urea is dissolved in 50 per cent. sulphuric acid, producing the characteristic yellow colour, and is then oxidised by means of potassium permanganate quantitatively, when the colour is discharged. The end point is quite sharp. The

ESTIMATION OF BLOOD UREA.

0.5 to 1 c.c. of blood is drawn from the patient and oxalated to prevent co-agulation. The blood is then deproteinised by the method of Folin and Wu. To one volume of blood is added 7 vols. of water, 1 vol. of $2\frac{1}{3}$ N sulphuric acid and 1 vol. of 10 per cent. sodium tungstate solution. Shake and filter on a dry filter.

Arrange a series of test tubes, 14 in number, of uniform size and make in a test tube rack. Mark the test tubes according to order as 1, 2, 3, 4, 5,.....14.

In the test tube No. 14 take 2 c.c. of the blood filtrate (= 0.2 c.c. of blood). Prepare a solution of tungstic acid by mixing 3 c.c. of $2\frac{1}{3}$ N sulphuric acid with 3 c.c. of 10 per cent. sodium tungstate solution and then adding 21 c.c. of distilled water to make up to a volume of 27 c.c. To the test tubes in the rack add the reagents as mentioned below:

TABLE I.

Test tube number:	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Standard urea solution; in c.c.	0.8	0.6	0.4	0.3	0.25	0.2	0.15	0.13	0.1	0.08	0.05	0.03	0	0
Tungstic acid solution; in c.c.	1.2	1.4	1.6	1.7	1.75	1.8	1.85	1.87	1.9	1.92	1.95	1.97	2.0	2.0 of blood filtrate only
Glacial acetic acid; in c.c.	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0
Amount of urea N; in mgm.	0.224	0.168	0.112	0.084	0.07	0.056	0.042	0.036	0.028	0.022	0.014	0.008	0	Unknown.

method described in the present paper is a clinical method and utilises the fact that while the excess of xanthidrol remains in solution in acetic acid, the precipitate of dioxanthidryl urea forms a cloudiness or turbidity proportional to the quantity of precipitate formed when the precipitate is suspended by shaking. It is thus possible to estimate the quantity of urea directly and fairly accurately for clinical purposes by comparison with the turbidity produced by solutions of urea of known strengths when similarly treated with xanthidrol.

Reagents and Apparatus.

(1) Folin and Wu's deproteinising reagents:— $2\frac{1}{3}$ N sulphuric acid; 10 per cent. sodium tungstate solution and distilled water.

(2) Standard solution of urea in water:—28 mg. of urea N (i.e., 60 mg. of urea) per 100 c.c. Add a little xylene as a preservative.

(3) Glacial acetic acid.

(4) Five per cent. solution of xanthidrol in methyl alcohol.

(5) Test tubes of uniform size and make in a rack: one 15-c.c. Folin's pipette; one 1-c.c. pipette graduated into $\frac{1}{10}$ ths c.c.; one 2-c.c. pipette; filter papers; glass funnel; one 25-c.c. graduated cylinder.

(6) Potassium oxalate crystals.

Mix. To each of the test tubes from 1 to 14 add 0.4 c.c. of 5 per cent. xanthidrol solution in methyl alcohol.

Let it stand for 5 minutes. Then stir the contents of each test tube with a glass rod. Wait for 45 minutes. The test tubes are then shaken to suspend the precipitate formed. The density of turbidity in each test tube is proportional to the quantity of dioxanthidryl urea formed and this in turn depends on the amount of urea present.

Calculation.—2 c.c. of the blood filtrate corresponds to 0.2 c.c. of blood (i.e., a dilution of 1 in 10). With the addition of an equal volume of acetic acid we have a dilution of 1 in 20.

Let us assume that the examined sample of blood filtrate matches exactly the test tube No. 6 of the standard set. Then the concentration of urea is the same in the two test tubes.

Now the concentration of urea in this test tube (No. 6), is 0.056 mg. of urea N in 4 c.c.; i.e., 1.4 mg. per 100 c.c. Since in dealing with the blood filtrate we are really dealing with a 1 in 20 dilution of the blood, the value for urea N is 20 multiplied by 1.4 mg., i.e., 28 mg. per 100 c.c. of blood.

* This 15-c.c. pipette is not essential.

For simplicity to get the value of urea N, simply refer to the following table:—

TABLE II.

					Urea N per 100 c.c. of blood.
Unknown matches with Standard No.	1				112 mg.
" " " " "	2				84 mg.
" " " " "	3				56 mg.
" " " " "	4				42 mg.
" " " " "	5				35 mg.
" " " " "	6				28 mg.
" " " " "	7				21 mg.
" " " " "	8				18 mg.
" " " " "	9				14 mg.
" " " " "	10				11 mg.
" " " " "	11				7 mg.
" " " " "	12				4 mg.

Example:—Unknown matches exactly with test tube No. 9 of the standard set. Then refer to the urea N value corresponding to No. 9 test tube which is 14 mg. of urea N per 100 c.c. of blood.

When the turbidity does not exactly match with any particular test tube, for example when it appears to be greater than one and less than the preceding one in the series, the mean value should be taken.

Laboratory Methods.—In this connection it may be mentioned that we have estimated the blood urea colorimetrically by dissolving the precipitate of dioxanthidryl urea in 50 per cent. sulphuric acid as advocated by Beattie. Instead of washing the precipitate in a Gooch crucible, we have removed the excess of xanthidrol by centrifuging as done by Luck. The supernatant fluid is decanted off. The precipitate is then washed with methyl alcohol preferably saturated with dioxanthidryl urea,—centrifuged again and the supernatant fluid is again decanted off.

The precipitate is finally dissolved in 50 per cent. sulphuric acid with the production of the characteristic yellow colour. The urea is then estimated colorimetrically.

We have estimated the urea in the same blood filtrate by (i) the urease method (according to Folin and Wu, using urease paper and distillation but finally titration), (ii) by the colorimetric method as above described, and (iii) by the present method, and we have found the present method to be quite reliable for clinical purposes.

As this method requires practically no special apparatus and the estimations can be done within one hour, it is hoped that the method will be of some service to the medical profession especially in remote and far off places.

Instead of matching the turbidity the precipitate can be allowed to settle and the bulk of the precipitate formed can be compared for urea estimation—a procedure similar to that adopted in the estimation of albumin in urine.

Summary.—A simple reliable blood urea method, suitable for use in remote places or even at the bedside, is described.

The advantages of this method are:—

(1) No special apparatus is necessary.

(2) The reagents used are quite stable and can be easily prepared.

(3) The results obtained are quite reliable for clinical purposes.

My best thanks are due to Dr. J. C. Saha, B.Sc., M.B., for helping me to carry out the check experiments.

Results obtained by the present method* for solutions of urea of known value and blood urea N values obtained by this method compared to values obtained by the urease—distillation—titration method are given below:—

Blood filtrates. (Hospital cases):		Present method:	Urease method:
1		5.5 mg.	5.5 mg.
2		16.0 mg.	16.8 mg.
3		31.5 mg.	30.8 mg.
4		5.5 mg.	5.6 mg.
5		9.0 mg.	8.4 mg.
6		163.0 mg.	159.6 mg.
7		70.0 mg.	64.4 mg.
8		24.5 mg.	27.6 mg.
9		14.0 mg.	15.1 mg.
10		28.0 mg.	28.0 mg.
Urea Solutions.†		Present method.	Known value.
1		31.5 mg.	28.0 mg.
2		42.0 mg.	42.0 mg.
3		14.0 mg.	14.0 mg.
4		7.0 mg.	7.0 mg.
5		19.5 mg.	21.0 mg.
6		28.0 mg.	28.0 mg.
7		14.0 mg.	14.0 mg.
8		9.0 mg.	8.4 mg.
9		49.0 mg.	50.4 mg.
10		56.0 mg.	61.6 mg.

Folin (1925). *Laboratory Manual of Biological Chemistry*.

Fosse, Robyn and François (1914). *Compt. Rend. Acad. des Sciences*, p. 367; quoted by Beattie, and by Luck.

* Standards of intermediate values may be interpolated between standards No. 1 and 2; 2 and 3; and 3 and 4 for more accurate results. In cases of blood urea values greater than 112 mg. per 100 c.c. of blood, dilute the suspension by adding carefully a measured quantity of solution (11 c.c. of which consists of 5 c.c. of tungstic acid solution, 5 c.c. of glacial acetic acid, and 1 c.c. of 5 per cent. xanthidrol solution in methyl alcohol) till the suspension will match as regards turbidity with the standard (Mukherjee, 1929). The diluting solution may be saturated with dioxanthidryl urea.

The blood urea value is calculated from the dilution or total volume of the unknown.

Example:—Unknown (Original volume = 44 c.c.) had to be diluted to a volume of 6.4 c.c. by the addition of 2 c.c. of the diluting fluid to match exactly with standard No. 1. The blood urea N = $\frac{6.4}{4.4} \times 112$ mg. per 100 c.c. of blood = 163 mg. per 100 c.c. of blood.

RESULTS OF EXPERIMENTS WITH CRUDE OIL PRODUCTS OF THE BURMA OIL CO., LTD., RANGOON, AS LARVICIDE.

By E. S. FEEGRADE,

*Military Assistant Surgeon, The Harcourt Butler
 Institute of Public Health, Rangoon.*

"BAUXITE extract," "Distillate Fuel," and "Victoria kerosene"—all proprietary preparations of The Burma Oil Co.—were the subjects of laboratory experiments to ascertain their anti-larval properties and as to which of the three products was most effective in the smallest quantity when spread over a measured surface of water. They were employed side by side with controls.

Larvæ of *Aedes argenteus* were the only species obtainable in the numbers necessary for this experiment, and large ones of equal size were usually chosen.

After a series of experiments had been conducted, it was noted that—with a measured quantity of each of the products—the results varied on different days, although the conditions of the experiments were apparently exactly similar in every instance. Eventually it was discovered that the varying results were relative to the varying room temperature. Thus a high room temperature of 90°F. and above diminished the quantities of oil by evaporation and the anti-larval action decreased correspondingly, whereas a lower temperature gave better results in shorter periods.

The ultimate findings as to the minimum amount of each oil-product required to destroy *Aedes argenteus* larvæ were based on experiments carried out with 1,760 c.c. of tap-water, with a surface measurement of 6½ inches by 3½ inches and 4 inches deep, and a temperature varying from 85°—88°F. from 10 a.m. to 3 p.m. In this case the addition of 0.1 c.c. of "Victoria kerosene" killed the first larva in 40 minutes, and the last of 10 in 3 hours and 20 minutes; whereas with the same quantity of "Distillate Fuel" the first larva died in 30 minutes and the last after one and half hours; and with "Bauxite extract" the first larva succumbed in 20 minutes and the last after one hour and 10 minutes.

Smaller quantities than 0.1 c.c. of any of these three products gave unsatisfactory results, destroying some larvæ in longer periods, but not affecting others for three or four days, whilst in some instances pupation occurred.

Hence "Bauxite extract" stands first in the order of efficiency, then "Distillate fuel," and lastly "Victoria kerosene."

Further observations regarding the relation of temperature to experiments on such lines are necessary in order to arrive at more definite conclusions, so I propose to undertake these later on in the coldest and hottest seasons in Rangoon.

A Mirror of Hospital Practice.

A CASE OF MEDICO-LEGAL INTEREST.

By M. UMAR,

Bijnor, U. P.

A MAN from Kiratpur, district Bijnor, Bania by caste, was sent by the court for examination of his injuries on 13th February, 1929. He said that he was hit with a *lathi* (stick) on Monday, 11th February, 1929, afternoon. He had the following injuries:—

(1) A contusion six inches long and one inch wide just behind the right ear.

(2) A contusion over the upper part of the left arm eight inches long and two inches wide.

These injuries at the first glance appeared to be trifling. However, he further stated that blood came out of his right ear, nostril and mouth, and that he became unconscious when he received the blow. Although lying is very common in this country, I examined the right ear which was full of blood. Unfortunately it was a cloudy day, and I had to use artificial light; even then I could only see with difficulty. There appeared to be a small rent in the tympanum of which I was doubtful. Next day it was bright and I examined him in the sun, after washing the ear well; the condition was as shewn below:—

Condition on 13th February,

Congested area, spotted black.

Blood was oozing from the shaded area.

Now there are two causes of this injury, one direct and the other indirect. The injury to the tympanum was due to an indirect cause. Since he became unconscious from the blow there is probably a very fine fracture of the middle fossa of the skull, probably involving the Eustachian tube.

My reasons for inferring a fracture of the middle fossa is that the bleeding was probably from the Eustachian tube, which would allow blood being discharged from all three points, ear, nose and throat.

In this case the rupture appeared to be in the postero-inferior quadrant of the drum and it is sufficient to consider the injury as *grievous* on this account alone.

A CASE OF VOLVULUS OF THE LARGE INTESTINE AT THE SPLENIC FLEXURE.

By T. S. DAKSHINAMURTHI, I.M.B.,

*Sub-Assistant Surgeon, Alipuram Jail Hospital,
Bellary Cantonment, Bellary.*

A CONVICT Moplah, aged 66 years, was admitted to the jail hospital at 10 a.m., on 29th October, 1928, for colicky pain in the abdomen with a history of not having passed a motion within the previous 24 hours. The pulse was normal and 72 per minute. There was neither rigidity nor distension of the abdomen. He was given an ounce of castor oil at once which did not work his bowels. At 11 a.m. a turpentine enema was given with no result. By about 2 p.m. the abdomen was slightly distended. Discomfort increased and pain was localised to the upper abdomen. There was no marked rigidity. By 5 p.m. the abdomen was very much distended. There was definite rigidity and tenderness of the whole upper abdomen. The patient was feeling acute discomfort and was restless. Distension was more marked on the right side and the distended coil of the intestine could distinctly be felt. There was acute obstruction in the intestine with no passage of stools and flatus. His temperature was 98.8° and pulse full and 46 per minute.

The patient consented to the immediate operation proposed by the medical officer. He was anaesthetised and the abdomen was opened by a vertical incision 5 inches long in the upper abdomen about 1 inch to the right of the middle line. The transverse colon, which was much distended and congested, presented itself through the wound. The obstruction was, therefore, located below that portion. On search, a twist of the large intestine at the splenic flexure was discovered, the lower end of the loop lying over and across the upper one. The twist was released. The accumulated gas was expelled through the anus by careful pressure on the distended coil of the intestine and the abdomen was closed. The operation took only ten minutes and was done by the medical officer. The patient made an uneventful recovery.

The interesting points in the case are the following, viz:—

(1) The comparative rarity of a volvulus of the large intestine at the splenic flexure. It is stated in the textbooks that volvulus of the large intestine is common at the sigmoid flexure and the cæcum.

(2) For his age, the patient took chloroform very well.

(3) The necessity for surgical interference as early as possible in all cases of acute abdomen, in spite of age and other conditions of the patient, as surgery alone has a chance of giving him life.

My respectful thanks are due to my medical officer Dr. T. J. Gibson, I.M.D., who kindly permitted me to publish these notes.

TIGER BITES AND THEIR TREATMENT.

By K. G. KHANDEKOR, M.B., B.S.

Guna, Gwalior State.

RECENTLY I had to treat a dozen patients who had been mauled by tigers or leopards. It was not possible to treat all of them with serums, and iodine injections were only of limited use. So I had to fall back on some local application, and compresses of saturated solutions of magnesium sulphate were found of very great use. Pathologically, injuries caused by the teeth of the claws of these animals are of the nature of cellulitis. Wet compresses were applied over the inflamed parts and cavities containing pus were dressed with gauze soaked in the solution till the superficial inflammation had subsided (it usually took five or six days). Then no gauze was introduced into them, and the cavities healed promptly without any more discharge.

The temperature of the patients did not rise appreciably.

One patient was mauled by a tiger and his whole body was in a condition of surgical emphysema; he had no fracture of the ribs; the condition was probably due to gas-producing organisms. I was afraid to give him any intravenous injections as his veins could not be steadied and there was a danger of carrying some of the germs into the circulation along with the needle. The emphysema completely disappeared within four days by dressing the injuries with the solution of magnesium sulphate.

A FURTHER NOTE ON THE ACTION OF HÆMOPLASTIN.

By KAMAKHYA PROSAD LAHIRI, L.M.S.,

P. O. Bera, Dist. Pabna.

ABOUT four years ago, in April, 1925, a short contribution from the pen of the present writer appeared in this journal, under the caption "Hæmoplastin in Hæmorrhage." In this he reported favourably on the subcutaneous use of this hæmostatic in two cases of obstinate bleeding.

The patient who had uterine bleeding is still alive; she has had no further trouble from that cause. The patient who suffered from hæmorrhagic piles is also alive; he had a relapse of bleeding last year and another in the year previous to that. On both these occasions he was cured with hæmoplastin. Considering the unfavourable nature of the family history, he

now always keeps with him a few ampoules of hæmoplastin as a precautionary measure.

Last year the present writer had a case of epistaxis in an old man of 80 years. The loss of blood was very severe and it came on without any apparent cause. He adopted some of the usual measures recommended but without any appreciable benefit. The patient was not at first ready to bear the expense of treatment by hæmoplastin, so normal horse serum was given subcutaneously, but without any effect. As his condition grew worse, the patient agreed to the use of hæmoplastin. Administration of two subcutaneous injections of 2 c.c. each, at an interval of 24 hours, cured the patient.

A case of hæmorrhoids with profuse hæmorrhage was also treated successfully with this serum. The subject was a teacher, aged 40; three injections cured him.

A Bengali Hindu gentleman aged about 45 years was placed under the writer's treatment for severe hæmoptysis which he had had for three days. He was given calcium lactate and other drugs by the attending physician, but without any effect. On examination a few râles were audible with the inspiratory sounds at the right apex. The expiration was heard over the same area. The heart was healthy. Two injections of hæmoplastin in 2-c.c. doses stopped the bleeding.

Hæmoplastin being an animal protein, there is danger of its producing protein shock if the subject be hypersensitive to it. Dr. Pickering gives two examples of fatal shock in his book (*The Blood Plasma in Health and Disease*). Fortunately, the writer has not as yet met with a case of shock either mild or severe. Of course these examples will make him cautious in the use of the hæmoplastin in future, but will not deter him from its administration when life is threatened by hæmorrhage. The same risk is run in use of all antitoxic sera.

A HUGE OVARIAN CYST.

By ASST. SURGN. RAI SAHIB CHHAGAN NATH,

Officiating Residency Surgeon, Mewar, Udaipur.

CASES of ovarian cysts, though not very common in this part of the country, are met with now and again in hospital practice. The patient usually presents herself with a considerable abdominal enlargement, as admission to a hospital is only sought when all sorts of quack remedies, potion for ascites, and even waiting for pregnancy prove futile.

History.—The following is the history of the case. J., Hindu female, aged 40, married, nullipara, residence Entally, Mewar, was admitted to the Lansdowne Hospital, Udaipur, on the 14th September, 1928. She noticed gradual enlargement on the left side of her abdomen, which for the last two years had become very prominent. The abdomen had a spherical appearance, and a hard lump was felt on the left side, below the costal margin; the lump could easily have been mistaken for an enlarged spleen.

The circumference round her umbilicus was 44½ inches, and the measurement from the ensiform cartilage

to the symphysis pubis 20½ inches. She had an emaciated look. Her urine was normal. On internal examination there was no abnormality of the uterus. Her menstrual periods were normal and regular.

Operation.—After thorough preparation, the patient was placed on the operation table, and an incision of about 4 inches was made in the median line below the umbilicus. After separation of the skin and recti, the peritoneal coat was divided. The anterior aspect of the cyst-wall was then surveyed with the hand.

On searching for adhesions the omentum was found at some places sticking to the sac and could not be removed. A small band was found on the left side, which was ligated and snipped. A Spencer-Wells' ovariectomy trocar was then plunged into the cyst-wall, and the fluid evacuated, but the evacuation was not as much as expected, as another big cyst was found inside it. This was also punctured and evacuated through the main cyst, care being taken that no fluid contents entered the abdominal cavity.

Description of the cysts.—The sac was then gradually pulled through the opening, the pedicle securely tied and cut. The pelvic cavity and the walls were sponged dry. The abdominal wound was sutured in the usual way.

On examining the sac, six more daughter cysts were found in it, containing fluid of different colour and consistency. The fluid in the main cyst was of a dark brown colour containing a degenerated cheesy mass, three contained clear rosy fluid, like saliva, two had sebaceous matter, one contained fluid like bile, and the one which was in the splenic region contained a tuft of hair and a rudimentary tooth.

Weight of the fluid was 31 lbs., 4 ozs.

Weight of the sac was 3 lbs., 1 oz.

Weight of the hair and tooth 5 drs.

Making a total weight of the cyst equal to 34 lbs., 5 ozs. 5 drs.

The sutures were removed on the tenth day, the wound healed by first intention, and the patient made a rapid recovery. After operation she developed a voracious appetite, but this had to be controlled. Three weeks after the operation she was allowed to go home, as she

was very desirous to celebrate the *dhasera* festival at her own home as a 'new' woman.

My thanks are due to Dr. Sunder Lall, M.B., B.S., for his assistance.

SUMMARY.

The interesting features of this case are:—

(1) The huge enlargement of the abdomen, with a comparatively short history of two years.

(2) The solid feel of the lump on the left side resembling an enlarged spleen.

(3) The presence of a cyst inside a cyst; and the other half a dozen cysts each containing a different kind of fluid.

(4) Her great desire for food soon after the operation.

A FURTHER CASE OF DIAPHYSIAL ACLASIS, (MULTIPLE EXOSTOSIS) WITH A MARKED FAMILY HISTORY.

By H. STOTT, M.D., M.R.C.P., D.P.H.,

LIEUTENANT-COLONEL, I.M.S.,

Physician and Professor of Pathology,
and

P. A. SHUNANDAN LALL, M.B., B.S.,

Radiologist, King George Medical College, Lucknow.

IN the *Indian Medical Gazette* of January 1929, we reported seven cases of diaphysial aclasis (multiple exostosis) in Indians, including four cases from one family. The present case showed an even more marked family history, there being some 10 cases amongst 26 close relatives.

Hasan Mohamed Khan, aged 45, was admitted into King George's Medical College Hospital, Lucknow, in January 1929, for lung tuberculosis.

Fig. 1.

On physical examination, the following bony projections were noted:—

1. The lower end of the right femur was markedly enlarged with an obvious bony projection on the mesial side. (See X-ray Fig. 1.)

2. At the lower end of the left radius and left ulna. (See X-ray Fig. 2.)

3. A prominent bony lump, the size of a hen's egg from the cervical vertebra. (See x-ray Fig. 3.)

Fig. 2.

4. Some thickening of the acromial end of the left clavicle.

The patient states that the swellings have been present from his childhood without inconvenience, except that he attributes the cervical exostosis to injury produced some 13 years ago by the fall of a weight which he was carrying on his head and which struck his neck. He believes this lump has been growing larger of recent years. The whole of the left lung and also the right apex were the seat of extensive tuberculous disease and x-ray confirmed considerable infiltration in these areas. The family history is set out in the following chart where ♂ signifies male, ♀ female, whilst a circle round these signs signifies that the individual was suffering from this disease.

Fig. 3.

A CASE OF TYPHOID FEVER, RELAPSE. TOXÆMIC COLLAPSE AND RECOVERY.

By CH. KRISHNAMURTHY, L.M.P.,

Sub-Assistant Surgeon, Central Jail, Rajahmundry.

K., ADMITTED for fever on 5th March, 1928. Blood examined—no malarial parasites found, leucopenia. He was given a few fractional doses of calomel as his tongue was coated and put on alkalies and quinine after Sinton's method. The temperature was normal on the morning of the 8th (see chart attached). Again from the same evening it began to rise, and from the 13th his pulse began to get weak. Tepid sponging every 3 hours and camphor in oil injections every 8 hours were added to the treatment, while glucose, 2 drachms every 4 hours, was also given. As the pulse was very quick, digitalis was added to one of the mixtures. There was bronchitis from the fifth day of the illness and a rosy red rash was seen on the chest and back on the 9th day. Blood was sent for the Widal reaction on the 10th day; it was reported positive to *B. typhosus* on the 14th day. Quinine was stopped and alkaline treatment alone continued while urotropine was given separately. All the time the patient was put on barley water and milk and plain water to drink freely. He became normal on the 24th day of his illness and continued so till a week later. On 3rd April, 1928 (30th day from the beginning) he started to have a temperature, 101.6°F. in the morning, rising higher in the evenings. The pulse was again feeble and rapid; and suddenly on 6th April, 1928 his temperature fell to 99°F., the pulse became thready, 158 per minute and, the body cold and covered with sweat. The abdomen was slightly distended and he complained of slight pain on the right side. The usual treatment for tiding over collapse was given, such as hot-water bottles, an injection of adrenalin and pituitrin, and brandy by the mouth. He was already having digitalin injections and camphor in oil daily. His pulse

was no response; the patient died on the 18th. Unfortunately autopsy was not possible.

The question is, was this a case of cerebral malaria which proved refractory to quinine and plasmoquine or a genuine case of acute encephalitis lethargica? Could it have been a case of typhoid (note the slow pulse and continuous fever in spite of the negative Widal reaction) together with a severe attack of malignant tertian? Was it a case of heat stroke though the climatic conditions under which she lived could hardly suggest this?

We are indebted to Dr. P. C. Bharucha, M.D. (Lond.), for his valuable help in reporting this interesting case.

ROUNDWORM INFECTION SIMULATING APPENDICITIS.

By B. SUKHAVANAM, L.M.P.,

Sub-Assistant Surgeon, Gadizemuly P. O.

S. S., male, age 35, Mohammedan, came to this dispensary for treatment of pain in the right iliac fossa on 7th December, 1928.

Ten days before he had had acute pain in the right iliac fossa. He went the headquarters station and sought treatment under a medical practitioner. He says he was given 3 injections (probably morphine) which relieved him and soon after he returned to his native village. Three days afterwards, he developed similar acute pain over the same region which was more acute than the previous one. Finding no relief after trying various indigenous drugs, he sought treatment in this dispensary, three days later.

The following was his condition on admission:—

(1) A fairly well-built man of 35 with an agitated facial expression due to the present condition.

(2) Pulse, 100.

(3) Temperature, 99.8°F.

(4) Tongue, coated.

(5) A distinct swelling at about McBurney's point which was also tender.

(6) Slight rigidity of the abdomen.

I ordered hot fomentations to the abdomen and an enema; to my surprise, the patient passed a roundworm after the enema was given and he even vomited one roundworm in my presence.

Hot fomentations were, however, repeated. In the night the following was given:—

Santonin	gr.	i.
Calomel	gr.	iii.
Soda bicarb.				gr.	iv.

at bedtime, followed by castor oil on the following day. He passed several worms the next day and all the acute symptoms passed away. After observation for 3 days, he was discharged cured.

The main point of interest is that the symptoms and signs simulated appendicitis but were apparently due to roundworm infection.

A CASE OF SUPPRESSION OF URINE.

By B. SUKHAVANAM, L.M.P.,

Sub-Assistant Surgeon, Gadizemuly P. O.

I was called in to see a patient in a village 3 miles away on 25th January, 1929. The person

who came to call me stated that the patient was suffering from retention of urine for the last 12 hours.

When I saw the patient at 8 a.m. on January 25th, the following was his condition:

The patient aged 28 years was in a condition of deep shock.

(1) Abdomen, distended.

(2) Pulse, weak and thready.

(3) Temperature, 97.8°F.

(4) Face, pale, sunken eyes.

On palpation of the abdomen no hardness or any localised swelling could be made out, especially over the region of the bladder, to account for the complaint—retention of urine. To clear my doubt, I introduced a catheter to draw out urine. Not a drop of urine could be drawn out. There was complete suppression of urine.

Meanwhile his general condition was threatening and so I gave pituitrin 1 c.c. hypodermically. An enema was also given which, however, did not act. The patient died at one o'clock the same day.

In this connection it may not be out of place to say that the native village of the patient was infected with cholera three months previously, and it has got an unprotected water supply from an open channel.

The sudden onset and rapid death within 19 hours after the attack suggests this to be case of cholera sicca, rather than intestinal obstruction in which a patient is known to live for 6 or 7 days after the onset of the symptoms. If it is a case of cholera sicca, the distension of the abdomen must be accounted for.

SPECIAL ARTICLE.

SOME REFLECTIONS ON OBSTETRICS AND GYNÆCOLOGY DURING 1928.

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P. (Lond.),
LIEUT.-COL., I.M.S.,

*Professor of Obstetrics, Calcutta Medical College, and
Surgeon to the Eden Hospital.*

OBSTETRICS.

Diabetes in Pregnancy.—Until recently the prognosis of a diabetic patient as regards conception and pregnancy has always been grave, the toxæmia tending to cause premature delivery, death of the foetus, or coma. Puerperal sepsis in these patients is almost invariably fatal, but to-day, if a patient is treated with insulin and scientifically dieted, there is no ground for terminating pregnancy, and no reason why a living child should not be born. Puerperal complications are rare, and evidence has accumulated to show that pregnancy has no ill effects on the disease itself.

Mitral Stenosis in Pregnancy.—Séjourné, in a very able monograph on the subject of mitral stenosis in pregnancy, emphasises the fact that

radiological examination of the heart is necessary in order to determine the size of the left auricle before giving a prognosis. He lays down the dictum that if there be dilatation of the auricle, interruption of pregnancy is imperative even though there are no symptoms of cardiac distress or loss of reserve power. He warns against using ether in emptying the uterus and states that pregnancy should be forbidden in every case of mitral stenosis in which there has been a previous attack of oedema of the lungs. Our experience in the Eden Hospital bears him out, and I consider that in any case of mitral stenosis it is best to empty the uterus in the first two months of pregnancy, or at least warn the relations of the very grave dangers that are run by every patient who has this affliction.

Gall-bladder disease in Pregnancy.—Gall-stones are peculiarly common in females in the tropics, and particularly so among the wealthier classes who take little exercise and incline to eat rich food. The calculi are largely composed of cholesterol which is obtained from that excreted in the bile. During pregnancy there is always hypercholesterolaemia, and this predisposes to the formation of gall-stones, and may be the reason why the specialist and general practitioner so frequently is confronted with cases of gall-bladder disease during pregnancy. It should be our aim therefore to keep the blood cholesterol of all fat and well-to-do pregnant patients who have had symptoms suggestive of cholelithiasis at the lowest possible level.

The cholesterol of the blood is dependent in a large measure upon the diet, hence one method of accomplishing this purpose should be to reduce the ingestion of cholesterol bearing food. Such foods as fat, egg yolk, fried food, sweetbreads, liver, kidney, pork, oily fish, (*jilsa*), butter and cheese, should be omitted from the diet.

Placenta Accreta.—Nathansen draws attention to the fact that there is a condition of placenta accreta where the placenta is so attached to the myometrium that no spongy layer exists as an intervening space between the chorionic villi and the muscle of the uterus. This pathological anomaly occurs about once in twenty thousand cases, and if not recognised with the hand in the uterus, may be the cause of disastrous rupture of the organ when attempting to remove the placenta. He is of the opinion that placenta accreta can occur any time after the first month, and is most usually found—according to the literature on the subject—at the tubal angle and over the site of a submucous fibromyoma. The condition should be suspected if in any case of adherent placenta (1) there is no uterine bleeding, (2) there is no descent of the umbilical cord, and (3) there is no characteristic ball-like condition of the fundus. Should these three conditions be present, no attempt at Cr  d   delivery should be made. With every aseptic precaution, the uterus should be explored and if no line of cleavage is found to exist between the placenta and uterus, hysterectomy is the only rational

procedure, for by this means alone can rupture of the uterus be avoided, and the patient saved from death, which usually follows this catastrophe as the result of haemorrhage or sepsis.

As a proof against the futility of attempting to separate the placenta, Polak and Frankl have demonstrated *post-mortem* in two cases, that in this pathological and anatomical type of placenta accreta it is absolutely impossible to separate the placenta from the uterine wall.

The writer welcomes this contribution to scientific obstetrics, for he has on two occasions lost patients from this condition, which he now realises would have been saved had he recognised the condition in time and performed hysterectomy. He feels sure that every experienced obstetrician in India will be glad to know of this condition and its correct diagnosis and treatment. The records of the Eden Hospital during the last seven years, demonstrate that out of 8,500 confinements, there were 71 cases of retained or adherent placenta; of these 20 died, a mortality of 28.2 per cent. Looking back at some of these cases now, I am sure that a few were cases of placenta accreta which could have been saved by hysterectomy.

Hydatidiform Mole.—There seems little doubt that this condition is more common in the tropics than is generally recognised, therefore it will serve a useful purpose to consider recent work on this disease, for Teacher has found that malignant transformation of hydatidiform mole occurred in 36 per cent. of cases, whereas Hitchmann, in a record of 240 cases, demonstrated that malignancy occurred afterwards in 48 per cent.

Seeing that the primary mortality of vesicular mole by itself is 20 to 25 per cent., and that the mortality of operation on cases which have developed chorionic epithelioma is at least 60 per cent., it seems rational to "jib" at the textbook methods of treatment which are laid down for hydatidiform mole, and to state that the expectant method of treatment is not founded on a scientific basis, for complacent tardiness has not served to mitigate the primary mortality of the disease, nor thwart the development of secondary malignancy with its widespread metastases.

Therefore the pendulum in many countries is swinging towards active surgical treatment. Many advocate that laparotomy, and then hysterectomy with complete visual evacuation of the uterus should be done, others consider that according to the age and parity of the patient, complete hysterectomy is the ideal method of treatment.

Immediate Repair of Birth Canal Injuries.—Potter, Davenport and Bubis in America have written enthusiastically of the treatment of all injuries to the cervix and levator ani by immediate suture. They state that the anatomical results are better and that the patient is saved time and expense if the suturing is done either at once, following the third stage of labour, or during the first five days. Bubis even goes further and deals with old rectoceles and cystoceles and states that

the results justify the means, but such a procedure could only be carried out in a hospital, and therefore until such time as accouchements cease to occur in private houses, and are all done in hospitals properly equipped and staffed, it is unlikely that this American innovation will become popular.

Epidemic Encephalitis.—Roques, in the *Journal of Obstetrics and Gynæcology of the British Empire*, reports 21 cases and reviews the whole literature extant on this subject. The conclusions are—

1. Parkinsonism is liable to make its first appearance during or after pregnancy.

2. Parkinsonism frequently undergoes aggravation as a result of pregnancy, the aggravation taking place most commonly after early gestation or shortly after the confinement.

3. Parkinsonism does not cause sterility.

4. Pregnancy, labour and the puerperium are usually adversely influenced by Parkinsonism.

5. The children are almost always healthy at birth and apparently survive to live normal lives.

6. The termination of pregnancy is not to be advised for the following reasons:—

(a) that such termination does not benefit the course of the encephalitis;

(b) the mortality in the cases of artificially terminated pregnancies is the same as the average mortality of all cases.

(c) Cæsarean section is unnecessary for the sake of the child, except in a very small group of desperate cases in which the hope of saving the mother's life has been abandoned. Any operative interference in these cases is a very great risk.

7. Natural labour must be carefully watched for, for it may be completed without the knowledge of patient or attendants, with consequent risk to the infant.

8. The second stage should be completed as quickly as possible, using forceps if necessary. The mother should not nurse the baby.

Streptococcal Puerperal Septicæmia.—B. P. Watson reported an outbreak of virulent *S. hemolyticus* infection in the Sloane Hospital, New York; 24 patients were infected and 9 died. Every known avenue of possible source of infection was investigated, and eventually it was considered that the streptococcus which was found in the nose and throat of certain doctors, nurses, and members of the domestic staff, was the origin of the outbreak.

He considers that these members of the staff were the indirect carriers, and as a result, every attendant in the maternity wards and labour rooms should be masked in future. He notes that every patient but one who had a positive blood culture died.

It is interesting to observe that the treatment carried out was that which we use in the Eden Hospital, namely, a modification of the Gordon Luker method together with blood transfusion. It will be noted that the mortality of this virulent streptococcal epidemic was 30.7 per cent., even

though every scientific method of early diagnosis and treatment was at the disposal of the Director.

Failed Forceps Cases.—An interesting discussion arose at the B. M. A. meeting in 1928 on the above subject. Douglas Miller, Hendry, and Fletcher Shaw analysed 558 cases of unsuccessful forceps application. From the analysis of these cases it would appear that—

(a) One-third were due to disproportion between the head of the foetus and the pelvis. In this group there were 29 maternal and 154 foetal deaths.

(b) One-third were due to occipito-posterior positions. In this group there were 16 maternal and 100 foetal deaths.

(c) One-third were due to anomalies of the soft parts and premature application of the forceps. In this group there were 9 maternal and 78 foetal deaths.

These astounding statistics, comprising 54 maternal and 332 foetal deaths, forcibly demonstrate the urgent necessity for propaganda and higher education of doctors and the public, as to the necessity of ante-natal care and the real art of obstetrics. For there can be no question that these tragic and appalling results in the hospital class of patient can, and should be, obviated, and this can only be done through the public press, and the General Medical Council insisting on a standard of teaching and practical instruction higher than now exists.

The authors indicate that the individual causes of maternal death were: sepsis 37; rupture of the uterus 8; post-partum hæmorrhage and shock 6; and pneumonia 3. Moreover, they point out that in 133 cases, that is 23.6 per cent., the puerperium was morbid, and that the patients only recovered after many weeks of exhausting fever.

Including still-births and neo-natal deaths, 357 of the infants were lost, a mortality of 64 per cent. These statistics indicate that ante-natal care is in its infancy among the poorer classes, but they also indicate that the standard of professional and midwife skill must be at a low level.

In India, ante-natal care is as yet in the embryonic stage, and if such are the statistical results in the cities of Edinburgh, Glasgow and Manchester, one dare not contemplate what may be the silent death roll of maternity in the tropics. But just as Great Britain is awaking to the necessity of fuller education and ante-natal care, so I trust the enlightened *intelligensia* of India will privately or publicly, with or without the assistance of Government, take stock of conditions and begin propaganda for the prevention of maternal mortality, by instituting ante-natal centres run by competent doctors and midwives in every municipality.

A part and parcel of every such scheme should be that post-graduate courses for doctors and midwives of every community should be held regularly for a month, four times a year in the big Presidency towns which contain maternity teaching units.

In *extra-uterine gestation* with distension of the tube, and possible extravasation of blood into the peritoneal cavity, the area of extreme sensitiveness is of the size of the palm of one's hand, from the anterior iliac spine to the middle line on one side. (It may also be most marked at one shoulder tip.)

In *torsion of an ovarian cyst* the hyperalgesia is on *one* side only, and rarely involves an area larger than two inches diameter just above the centre of Poupert's ligament.

These abdominal clinical features are of special importance in India to general practitioners, who oftentimes are not permitted the facilities of making a more accurate diagnosis by vaginal examination. If they will bear these tests in mind, occasion may arise when they can anticipate or prognosticate catastrophe if expert surgical skill is not sought.

Polypi of the Cervix.—It is necessary to sound a note of warning to all clinicians on the subject of polypi presenting themselves at the external os of the uterus, for although a large percentage are mucous polypus or submucous fibromata, quite a definite percentage of these cases are malignant, the degree of malignancy varying according to the type of cell element present. Therefore it is particularly necessary to stress the fact that *every* polypoid mass projecting from the neighbourhood of the cervix should be submitted for expert opinion after removal.

How important this is, will be seen when I mention that during the last 24 months I have removed 21 so-called polypi which were sent to me by general practitioners. On clinical examination they were apparently all benign, but on section of each, five were definitely neoplasms, and in consequence the prognosis and treatment was a very different matter.

One was a typical endometrioma growing from the margin of the external os, one was a perfect specimen of an adenomyoma projecting by a stalk attached to the neighbourhood of the internal os. One was a sessile mass the size of a raspberry which proved to be a chorionic epithelioma, one was an adenocarcinoma in an unmarried girl aged 26 which clinically was a typical submucous polypus with a long stalk attached just above the internal os. One was a case of sarcoma botryoides. In three of these the pathological finding was to me an extreme surprise, namely, the adenocarcinoma, the adenomyoma and the sarcoma case. In two of them, namely the sarcoma and the chorionic epithelioma, the patients refused further operation and were seen four and seven months later respectively, *in extremis* with secondary growths in the abdomen and lungs.

Three patients had complete hysterectomy done, two of them have been seen eight and ten months later and the pelvis is clear. The case of adenocarcinoma is still in hospital after operation a few days ago.

I have considered it important to bring this matter to the notice of practitioners, for oftentimes polypoid growths of the cervix are seen and

complacently dealt with, and the growth not sent to the pathologist. Whereas they will see from the above cases how very serious and urgently important it is to obtain an expert opinion on every tumour growing from or in the neighbourhood of the uterine cervix.

Cox and Beneschek this year have recorded two cases of sarcoma botryoides, one in a child and one in an adult aged 29. In both, the clinical appearance was that of papilloma of the cervix, the tumours were removed locally for section and found sarcomatous. Hysterectomy was later performed, but in both cases the patients died of metastatic growths within a few months.

Maslen Jones also reports a case in a girl aged 18 which was dealt with locally and on section showed no evidence of malignancy, the diagnosis being mucous polypus. But five months later the patient returned with a large soft mass of semi-translucent polypoid bodies filling the vault of the vagina, which was inoperable. Six months later she died with pulmonary metastases. In his review of the case, he states that Paul Plett up to 1922 collected 36 published cases, and found that the age incidence of this virulent sarcoma was two and a half to fifty years.

He states that in the early stage of this neoplasm there appears to be no absolute evidence microscopically of the true nature of the growth, and that even when well formed the histological appearance of the polypus is so indefinite that where reliance is placed on this alone, radical operative treatment will be delayed too long.

While writing about morbid conditions of the cervix seen in recent years in Calcutta, I should like to call attention to the necessity of all general practitioners using a speculum and obtaining a good view of the cervix in women who complain of vaginal discharges, sanious or otherwise.

The reason I stress this point is that quite apart from the question of polypi or the early diagnosis of cancer, I have seen a considerable number of ulcers of the cervix which would have defied digital diagnosis solely.

For instance, I have records of four cases of early tuberculosis of the cervix, seen in consultation. I have seen soft based ulcers serpiginous in outline, which had no slough but exuded a thin ichorous discharge. In two of these, *Spirocheta pallida* were found, in one, typical Leishman-Donovan bodies were discovered, the condition being that of leishmania infection of the cervix, corroborated by finding the same bodies by spleen puncture. In several Ducrey's bacillus was isolated; in two patients who had early clinical leprosy there were ulcers creeping from the cervix on to the vaginal vault which gave a pure growth of *Streptococcus viridans*, although I expected to find the lepra bacillus. Possibly the bacillus would have been found, had a section of the cervix been permitted.

The lesson to be learned from these cases is that every ulceration of the cervix is a morbid process demanding expert diagnosis and treatment by knife, radium, cauter, or diathermy.

MAY.

RECENT RESEARCHES ON THE FILTRABLE VIRUSES.

THE diseases due to filtrable viruses constitute a medical problem both of the greatest importance and of the greatest difficulty. Yet three recent events show that slowly but surely medical science is grappling with this problem. The first is the publication in 1928 by Messrs. Baillière, Tindall and Cox of a symposium on our present knowledge of the subject, edited by Dr. T. M. Rivers of the Rockefeller Institute for Medical Research, New York.* We reviewed this volume on p. 46 of our January issue, and have relied largely for information here on Dr. Rivers' opening chapter of that volume, in which the subject of the filtrable viruses in general is reviewed. The second event is the final and triumphant report of the Field Distemper Fund and Research Committee, which has placed in the hands of dog-owners a really successful method of prophylactic inoculation against this disease. The third is the recent work of Dr. E. Hindle of the Wellcome Bureau of Scientific Research on a protective vaccine against yellow fever.

The diseases due to filtrable viruses are a very large and miscellaneous group comprising diseases of men, animals, birds, insects, and plants; in fact the only feature which such diseases present in common with one another is that the virus concerned is filtrable. Even diseases of bacteria due to bacteriophages should be included in the list. With regard to man the chief diseases here concerned are the common coryzal cold, influenza, small-pox and vaccinia, chicken-pox, infectious encephalitis, herpes, rabies, trachoma—probably, —measles, yellow fever, dengue—almost certainly, and the diseases due to rickettsia bodies (typhus, trench fever, Rocky Mountain spotted fever, Japanese river fever), in which the causative rickettsia parasites have been discovered and the mode of transmission of the disease is known. With regard to animals, distemper of dogs is the most important disease; others are foot-and-mouth disease of cattle, encephalitis of rabbits, Rous' sarcoma of chickens, pleuropneumonia of cattle and sheep and goats,—where the disease is due to a minute bacillus of Pasteurella type, which is filtrable,—the pernicious anæmia of horses, and virus III infection of rabbits. In insects, sacbrood of honey bees; wilt of the European nun moth, and wilt of the gipsy-moth caterpillar are due to filtrable viruses. In fowls

a most mysterious and acutely epidemic disease associated with a high mortality, which has spread from Great Britain within the last few years to India, and which appears to be common all over the world, is due to a filtrable virus.† The curious contagious epithelioma of fowls is also due to a filtrable virus. In plants the mosaic disease or infectious chlorosis, which often affects tobacco plants, is the best example. It is obvious that such a miscellaneous and heterogeneous collection of diseases is not a real classification on true ætiological lines; it is merely one due to the fact that all the viruses concerned are filtrable and of ultra-minute size. Future research will probably show the necessity for splitting up the group into different sections.

Modes of transmission of these diseases vary as widely as do the characters of the disease themselves. Some are extremely contagious (small-pox, coryza, and influenza); others (rabies) are conveyed by bites; others are insect borne (yellow fever, dengue, and yellows of aster plants); still others are only transmissible by grafting (infectious chlorosis of plants). Should the "patient" recover from the disease, an interesting feature is that he appears to have an immunity of a solid character (small-pox, vaccinia, measles, chicken-pox, e.g.), though this is not the case with influenza. The serum of recovered patients shows immune properties and is protective when inoculated into an exposed subject, yet such protective power is often of a weak order.

With regard to the real character of these viruses it is obvious that the viruses concerned must be of a living and particulate character, though usually invisible. d'Herelle considers that the bacteriophage has a diameter of less than 30 micro-microns. In brief these living organisms are almost approximate in size to the colloidal particles of fresh 1 per cent. hæmoglobin. With regard to cultivation of these viruses, the presence of living tissue cells in the culture medium appears to be essential, and the most successful results have been recorded with cultures in tissue plasma plus cells, following Carrel's method of cultivation of living tissues. On the other hand, a most curious feature of some of these viruses is their great resistance to desiccation; the virus in some instances may be infective after weeks of desiccation at room temperature (this suggesting the possibility of a spore or resistant-phase). Further, the viruses appear especially to attack young cells rather than mature ones; thus bacteriophage will cause lysis in young cultures of bacteria, but not in old ones.

Some of the viruses concerned exhibit a selective affinity for special tissues; thus vaccinia, small-pox, herpes, chicken-pox and contagious epithelioma of fowls attack the epithelial tissues, rabies and poliomyelitis the central nervous system, Rous' sarcoma the mesodermal tissues. The viruses are markedly cytotropic as a whole, and

* *Filtrable Viruses*. Edited by Dr. T. M. Rivers. M.D. Pp. 428 with several illustrations and 1 colour plate. 1928. London: Baillière, Tindall & Cox. Price, 34s. net.

† *Vide Calcutta School of Tropical Medicine Annual Report for 1928*, p. 32.

appear to be incapable of survival outside the cell. Further, they cause the most curious changes in the infected cells. The cell nuclei, poisoned apparently by the toxins of the disease, extrude nuclear fragments into the cytoplasm, where a cytoplasmic reaction takes place. Sometimes (as in contagious epithelioma and warts) the virus appears to cause hypertrophy and stimulation of the cell, sometimes, however, lysis and destruction of the infected cell (as in variola, small-pox and bacteriophage). The lesions in cells affected by the virus are usually both characteristic and specific, and (as in the Negri body of rabies) this appearance can often be utilised in the diagnosis of the disease.

What these cell inclusions are, opinion is by no means unanimous. Some regard them as the actual parasites themselves, but there is very scanty evidence to support this view; bodies of such large size should not be filtrable. Others regard them as products of degeneration in the cell, poisoned by the toxins of the disease; still others as evidence of the presence of the ultra-minute organism responsible, plus a cytoplasmic reaction on the part of the host cell. In the case of rabies reliance for diagnosis is placed on the Negri bodies in the cells of the hippocampus major of the infected dog; in the case of scarlet fever, on the other hand, the whole trend of recent evidence goes to incriminate a hæmolytic streptococcus as the ætiological agent, and to discredit the view that the Mallory bodies (cell-inclusions) have anything to do with the ætiological agent of the disease.

The whole problem is rendered still more complicated by the suggestion by Gye and others that cancer is due to a filtrable virus plus some other secondary predisposing factor—possibly present in the plasma of infected persons.

Most of the viruses concerned can be preserved in glycerine or in cold storage, and glycerine appears to act in this instance as a desiccating agent, retarding autolysis of the tissues within which the virus is conserved. They are inactivated by high temperatures, but not as a rule by extremely low temperatures. Some workers have even gone so far as to suggest that, owing to their general resistance to desiccation, the filtrable viruses must be inanimate in nature, but there is but little evidence to support this view. It is much more probable that they are living bodies of extremely minute size, not visible under ordinary microscopic powers (except for the rickettsia bodies).

This necessarily brief summary shows at once both our knowledge of the filtrable viruses and the immense lacunæ which exist in our knowledge of the subject; and Dr. Rivers' book is of the greatest value to the laboratory worker from many points of view—not the least of which are the valuable bibliographies appended to the different chapters.

* * * *

Faced with such a problem, what can the medical profession do by way of prophylaxis

against these diseases? The first lead was given long years ago when Jenner in 1796 introduced inoculation with cow-pox as a protective measure against small-pox. We wonder whether at that early era Jenner recognised the tremendous importance which future generations would attach to his discovery. The second step forward was the ever memorable discovery of antirabic immunization by Pasteur in 1885. Working entirely in the dark, with the most primitive of apparatus, Pasteur introduced the method of treating patients subject to infection at first with doses of dead rabies virus in the spinal cord of infected rabbits, followed by inoculations of the living virus of increasing intensity; it was one of the most notable experiments in medicine. This was followed by the introduction of the Hoëgyes' method of using dilutions of the fresh virus of gradually increasing strength; by the introduction of Semple and Harvey's dead carbolised virus (to-day in use in all the Pasteur institutes in India); and by the recent use of an ether vaccine, chiefly by Japanese and American workers.

Matters, however, have proceeded even further recently. Foot-and-mouth disease of cattle was studied in Great Britain by a special research committee appointed by the National Council for Medical Research, and they have now shown that protection can be afforded against that disease with a formalinized vaccine prepared from infected organs. The Distemper Research Committee (under the direction of Dr. Laidlaw and Mr. Dunkin of the National Institute for Medical Research, Hampstead) have shown that a solid immunity against distemper can be produced in dogs by inoculating them first with a vaccine made from dead virus, then with one made from an attenuated living virus. No less than 1,330 dogs under the care of 44 veterinary surgeons, and 325 couple of foxhounds have been inoculated and have proved resistant to infection under experimental or laboratory tests. It is hoped—writes the *Field* of 5th December, 1928—that this vaccine will shortly be produced on a large experimental scale by selected responsible biological chemists for sale.

Finally, come the recent series of papers of the last two and a half years dealing with the subject of yellow fever. Up to the middle of 1926 it was generally accepted that yellow fever was due to *Leptospira icteroides* Noguchi, 1919 (and a summary of the evidence in favour of this view is given by Knowles, 1928, p. 563). Several of the more careful American observers, however, have always doubted this evidence and have claimed that *L. icteroides* is identical with *L. icterohæmorrhagiae*, the cause of infectious jaundice or Weil's disease.

Theiler and Sellards (1926) appear to have been the first observers to conduct experiments directed to determine whether the two leptospira strains were or were not one and the same organism. They found that guinea-pigs immunised to either strain were completely protected against the other; and the possibilities raised by this

paper, as Dr. Wenyon notes in reviewing it, "are too radical for discussion." Sellards (March, 1927), next investigated Pfeiffer's phenomenon with reference to both *L. icteroides* and *L. icterohæmorrhagicæ*; he concluded that the evidence showed that the two were identical. Puttoni (May, 1927) concluded from cultural and serological observations that the two strains were one and the same. Sellards (July, 1927) in a review of the whole situation concludes that yellow fever and Weil's disease are two very different clinical types of disease; that *L. icteroides* is not the causative organism of yellow fever, and "if the patient's serum gives a positive Pfeiffer reaction with *L. icteroides* he is suffering from Weil's disease and not yellow fever." Brown and Davis (October, 1927) studied the adhesion phenomenon with reference to different leptospira strains; both *L. icteroides* and *L. icterohæmorrhagicæ* behaved alike. Sellards and Theiler (November, 1927) again investigated the Pfeiffer phenomenon and the protection tests with both *L. icteroides* and *L. icterohæmorrhagicæ*; they conclude that the former is synonymous with the latter. A negative reaction with *L. icteroides* is consistent with the diagnosis of yellow fever. Hosoya and Stefanopoulo (December, 1927) carried out agglutination tests, the Pfeiffer test on different strains, and immunization experiments; they conclude that *L. icteroides* and *L. icterohæmorrhagicæ* are identical. Schüffner, Mochtar, Proehoeman and Honig (1927) compared three strains of *L. icteroides* with strains of *L. icterohæmorrhagicæ* with regard to agglutination and lysis reactions; both behaved in the same manner; further, *L. icteroides* would not survive in the mosquito *Aedes ægypti* longer than the fourth day after the feed.

About this time the Rockefeller Foundation Commission on yellow fever in West Africa was formed and sent out—with the most tragical results, for Professor Adrian Stokes, Professor Noguchi and Dr. W. A. Young each in turn fell victims to and died from the disease which they were investigating. Stokes, Bauer and Hudson (January, 1928) appear to have been the first workers to establish the fact that the monkey *Macacus rhesus* is extremely susceptible to inoculation with yellow fever virus. This they further confirmed in March, 1928, and showed that *Macacus sinicus* is also susceptible, but to a less degree. Mathis, Sellards and Laigret (February, 1928) confirmed this, and found that the disease could be experimentally transmitted from monkey to monkey by infected mosquitoes. Meantime Baermann and Zuelzer (February, 1928) had carried out extensive researches with different types of leptospira, the result of which was to throw considerable doubt upon the diagnosis of species by serological tests; *L. icteroides* they found to behave in all respects as did *L. icterohæmorrhagicæ*. Schüffner (March, 1928), reviewing the whole series of papers and researches, concludes that *L. icteroides* is identical with *L. icterohæmorrhagicæ*; further, *L. icteroides* is

absent from the West African cases of yellow fever, although these are typical of the disease. Bruynoghe and Cornil (March, 1928) conclude "the results establish the biological identity of *L. icteroides* and *L. icterohæmorrhagicæ*, and in view of the clinical differences between Weil's disease and yellow fever, we are compelled to believe that the specific agent of this latter infection is still unknown"—a position which Sellards had taken up some time previously.

Further confirmation of this opinion is to be found in two other papers recently published. Neave Kingsbury (1927) has shown that *L. icterohæmorrhagicæ* will not survive in the stomach of *Aedes ægypti*, and if—as must now be taken to be proved—*L. icteroides* is identical with *L. icterohæmorrhagicæ*, then the former cannot be the causative agent of yellow fever. Still further. Kligler and Ashner (August, 1928) have shown that the mid-gut of mosquitoes of genus *Aedes* actually possesses the property of immobilising and destroying spirochetes of leptospira type. The present day consensus of opinion is that *L. icteroides* is identical with *L. icterohæmorrhagicæ*; that the few cases from which Noguchi succeeded in isolating leptospira were cases of Weil's disease occurring during an epidemic of yellow fever; that the causative agent of yellow fever is still undiscovered, and is of the nature of a filtrable virus.

Further results remain to be reported, however. Sellards and Hindle (April, 1928) found that frozen liver tissue and blood from a yellow fever case, imported from Dakar in North Africa to London, were still infective to *Macacus rhesus* monkeys, and that the virus would withstand freezing for at least twelve days. This enabled the disease to be established in *M. rhesus* monkeys in London for experimental purposes. Hindle (June, 1928) showed that a strongly protective vaccine could be prepared by grinding up the liver of infected monkeys in a formalinized or carbolised saline solution; a phenol glycerin vaccine gave solid immunity against the disease. This work follows closely upon the lines followed by the workers on fowl plague, dog distemper, and foot-and-mouth disease, and it would appear that the best vaccines against infections due to these filtrable viruses are to be obtained by formalinized or carbolised emulsions of organs of experimental animals infected with the disease. A consignment of some 200 *M. rhesus* monkeys was recently shipped from the Calcutta School of Tropical Medicine to Dr. Hindle in London, and it is to be hoped that a really efficient, protective vaccine against yellow fever in man is at last within sight.

* * * *

We have attempted to summarise as briefly as possible the trend of recent work upon the very important problem of diseases due to the filtrable viruses. At first sight this might seem to be unimportant to medical workers in India, but we believe its importance to India to be very great. Rabies, small-pox, the unsolved problem

of dengue (which presents such close analogies to yellow fever), influenza and coryza—these are all Indian problems of the first magnitude; and the research worker in India would do well not to neglect a study of what is being done in other countries towards solving the mysteries associated with the filtrable viruses. Lastly, it is not unlikely that such a study will help towards the elucidation of the cancer problem. Does the true ætiology of cancer involve three main factors: a filtrable virus, a hereditary tendency, and a local stimulus in the form of irritation?

(We cannot conclude these notes without acknowledging our indebtedness to the *Tropical Diseases Bulletin*, from which we have culled the fullest information).

ADDENDUM.

Abstracts of recent work upon the filtrable viruses.

DISTEMPER.

(The Times, 29th Nov., 1928.)

THE Distemper Research Committee are able to give a highly satisfactory account this morning of the results of their labours during the last five years. The scientific investigations which it describes have been carried out by Dr. P. P. Laidlaw and Mr. G. W. Dunkin, both of them in the service of the Medical Research Council; while the cost of the undertaking has been met partly by the Field Distemper Fund and partly by money voted by Parliament for medical research and administered by the Council, who have made substantial contributions in the shape of land, buildings, and labour. Thanks to the initiative of the *Field* newspaper and the efforts of all who have shared in the enterprise—to whom every dog-owner and dog-lover in the land must be deeply grateful—a secure addition has been made to the previous sum of knowledge on the causation of the disease, and new methods adopted for its prevention as the outcome of this advance have already met with practical success. But the prospective benefits of the inquiry do not end there. As the official chiefs of the *Field* and Medical Research Councils, the Duke of Portland and Lord Balfour, state in the preface to the report, the knowledge and experience gained will certainly have a wider value in the study and control of virus diseases in general, not only in other animals, but in men. The technical considerations involved in this last aspect of the inquiry—by far the most important of its results—need not as yet be examined in detail. It is enough to record the fact that the effort to find some means of preventing the disease which is the greatest curse of dog-life seems to have opened up a line of research which may prove in time to be of lasting benefit to human beings.

It is, however, in its special application to dogs that the immediate interest of the present report is to be found. The reason for its publication at this particular moment is that a point has been reached when it has been found possible to render them resistant to infection by distemper. That fact has now been proved beyond dispute once and for all. After examining the conflicting theories on the possible origin of the disease, the investigators accepted Carré's conclusion that the agent causing it is a virus or ultra-microscopic organism, and finally succeeded in making the animals immune against infection by a double inoculation, first with a vaccine which is the sterilised virus of distemper, and then with an attenuated strain of living virus. By this process 1,330 dogs, under the care of forty-four veterinary surgeons, have been successfully immunised against distemper, and 325 couples of foxhounds from fifteen different packs have been treated in the same way with the same satisfactory results. In the Puckeridge, to quote one report, twelve couples were inoculated in February of this year. In April distemper broke out.

but none of the treated hounds developed the disease, whereas of the uninoculated thirty-five couples contracted it and eleven couples died. The fact that results so encouraging have been attained after only five years of patient investigation, undertaken in the face of many and great difficulties, is a wonderful tribute to the scientific skill of the research workers and a most promising omen for further progress on the same lines.

The method of preventing distemper in any given dog consists of a double inoculation. Distemper occurs in dogs, not as was once supposed by a visible germ or micro-organism, but by an invisible one which is recognizable only by the virus or poison which is the sign of the organism's presence. The virus is the concomitant of the organism causing distemper in dogs and is present in all cases of distemper. The first inoculation of the dog which is selected for treatment is made with a vaccine which is in fact the virus of distemper made inactive by laboratory treatment. The second inoculation is made after an interval of about ten days with a weak or attenuated strain of the living virus. This dose of living virus is a hundredfold times as much as that which would suffice to infect any dog with distemper which had not been previously vaccinated with the first vaccine, or had not suffered from distemper already. But with a dog so vaccinated, the dose of living poison produces only slight symptoms, sometimes none at all, because it was rendered partially immune by the first vaccination. The second vaccination makes it completely and permanently immune.

The preparations of the vaccine and of the virus requisite for the inoculations are not yet available for distribution among the general public, or even among the veterinary practitioners, who are the proper people to employ them. But arrangements will be made for their production by responsible biological chemists on a scale such as will make them generally available.

FOOT-AND-MOUTH DISEASE.

(*British Med. Journ.*, 11th Aug., 1928, p. 268.)

THE third progress report of the Foot-and-Mouth Disease Research Committee is a bulky volume of 141 closely printed pages, relieved only by photographs of the new experimental station for work with cattle at Pirbright, and by a series of photomicrographs illustrating the histology of the foot-and-mouth lesion at various stages of its development. It opens with a most illuminating summary, compiled by the committee for the benefit of the Minister of Agriculture, of the new knowledge elicited by experts working at various centres under the direction of individual members of the committee.

Regret, tempered however with satisfaction, is expressed by the committee that so many members of the research staff have had to relinquish their work for the committee on their appointment to important permanent positions in the pathological world. It is pointed out that the training of competent workers takes time, and that lack of permanency of these research appointments will always seriously handicap continuity of research until the scientific veterinary service of this country acquires some very considerable accession to its permanent staff of workers. Some delay has occurred in connection with the contemplated experiments on bovines at the experimental station, Pirbright owing to the difficulty of securing absolutely efficient isolation of experimental units. It is hoped, however, that the new arrangements with regard to loose boxes and incinerators, the construction of which has involved much thought, will give the assurance of effective isolation, which is imperative if experimental results are to be confidently assessed.

The committee notes that many problems connected with the infectivity of cattle at various stages of the disease still await solution, but with the reconstruction of the experimental station progress in this important direction will, it is hoped, be rapid.

The new experimental data now available to the reader cover an extraordinarily wide range of subjects, and the hundred pages or so of small print which embody

the carefully compiled protocols and research summaries by the various members of the working staff may well appal all but the specialist in virus disease. For the others the admirable summary of the present state of knowledge compiled by the committee will afford not only ample food for reflection, but will convey the assurance that the knowledge already gained by sound, patient, and well-directed research has illuminated many dark corners, not only within the narrow bounds of foot-and-mouth research, but also within the vast sphere of virus disease in general. No student of the subject, therefore, can fail to be impressed by the mass of important data which have accumulated since the highly susceptible and inexpensive guinea-pig became available for foot-and-mouth investigation.

It is possible to sketch the new data only in the briefest form. Appendix I, written by F. C. Minett, n.s.c., M.R.C.V.S., contains details of the work carried out at the Ministry's Laboratory, New Haw. These reports deal with various problems of disinfection of virus-containing materials such as filtered vesicle fluid, various substrates of wood and iron with virus dried on their surfaces, hay, hides, and manure artificially impregnated with virus, the idea being to simulate natural conditions as closely as possible. Why phenol is relatively so inactive is not yet explained. Formalin and mercuric chloride also possess low efficiency in these three-hour exposure tests probably owing to their slower action. In the presence of added organic matter (saliva and faeces added to small pieces of virus-containing epithelium), and with a time limit of twenty-four hours, it was found that the disinfecting value of chlorine, iodine, and potassium permanganate was reduced one-thousand times, while the concentration of phenol, cresol, and formalin required for disinfection was not appreciably different in the two series of tests. Application of these results to the disinfection of artificially contaminated hay and hides showed that spraying of model haystacks with a 1 in 1,000 solution of formalin allowed to evaporate was very effective. The result is important in view of the experimentally ascertained fact that virus allowed to dry on hay has a long life. The soaking of artificially contaminated hides with 1 per cent. formalin for forty-eight hours was certainly efficient, but was prejudicial to the leather, and some other method must be sought.

Further work on the important question of immunization by means of formalized virus has been carried out, and it would appear that for the immunization of guinea-pigs no vaccine has proved superior to the formalized virus (contact with 0.1 per cent. formalin at 26° C. for forty-eight hours at pH 7.6). A single injection of this vaccine is followed by an immunity which can be recognized so soon as forty-eight hours, and it is effective up to two months. By "effective" is understood the inability of the living virus to produce secondary lesions in the body (tongue and feet) after introduction into the immunized animal by the usual intradermal route in the pad of a hind foot. Primary vesicle formation at the site of injection still takes place, and in this respect the artificially protected guinea-pig differs from the naturally recovered animal, in which neither local nor general symptoms appear in response to a fresh dose. There is a further difference in that the blood of vaccinated animals does not contain demonstrable viricidal antibodies, whereas no difficulty is encountered in demonstrating their presence in naturally recovered animals. Experiments in which large quantities of virus were given intravenously to normal, vaccinated, and naturally recovered animals, showed that in the two latter series no virus could be demonstrated in the blood after half an hour, whereas in the normal animal it could be recovered up to two or three days. It would seem, therefore, that in the case of animals vaccinated with modified virus, immunity to subsequent experimental infection is due to some profound alteration in the excitability of cell tracts (most probably of the reticulo-endothelial system) which are capable of responding at once to new infective antigen owing to their previous training or education by the formalized virus. The position is really on all fours with that of experimental pneumococcus or typhoid infection,

and, indeed, the more these viruses are studied the more do they seem to come into line with the visible bacteria in matters of pathogenesis. The formalized virus is believed to be dead by all criteria applied; yet it may not be so.

RECENT WORK ON THE FILTRABLE VIRUSES.

(Editorial, *British Med. Journ.*, 25th Aug., 1928, p. 346.)

IN spite of the difficulties that beset the experimental investigation of diseases belonging to the virus category, and particularly of those which affect man, knowledge appears to be slowly but steadily advancing in regard to this group of pathogenic agents. How widespread and varied are the activities of these viruses is well brought out in the recently published book by Dr. Thomas M. Rivers and his colleagues of the Rockefeller Institute at New York. In this book the present state of knowledge is set out concerning selected examples of viruses affecting respectively man, other mammals, birds, insects, and plants. Nor is the end necessarily there, for some authorities maintain that the bacteriophage associated with the names of Twort and d'Herelle is nothing else than an instance of an ultra-microscopic virus affecting bacteria themselves.

The chief interest to the medical reader, however, of recent work on viruses lies in the light it tends to throw on diseases of man brought about by agencies of this group. Here at present data are perforce limited, and, as the pitfalls are many, caution is particularly necessary. Nevertheless, some encouraging facts are emerging with regard both to prophylaxis and diagnosis. The important question whether it is possible to prevent a disease of the virus category by means of killed virus was apparently solved some years ago when rabies virus killed by phenol was successfully introduced into India for the prevention of hydrophobia; the credit for this advance is due to the pioneer work of Sir David Semple and his colleagues. Parallel but less convincing results in a preventive sense have from time to time been reported experimentally on animals with vaccinia virus inactivated by heat, and more recently by Knoepfelmacher and Stöhr in the human subject; it would seem that dosage is here an all-important factor and that repeated injections may be necessary for success. Moreover, according to its most recent report the members of the Foot-and-Mouth Disease Research Committee appear to have satisfied themselves that protection can be obtained against that disease with the virus after it has been killed by means of formalin.

A further direction in which progress is being made is in the application of serological methods to the diagnosis of virus infections. Experimental evidence has been furnished by a number of observers to the effect that specific antibodies occur regularly in the serum in cases of infection by the viruses of vaccinia and variola. We may note in particular that, according to Mervyn Gordon, in the serum of rabbits suitably prepared against vaccinia, specific antibodies showing an equal affinity for the viruses of vaccinia and of variola can be demonstrated by the complement-fixation test, and also by the agglutination or precipitin test. Evidence was found that serum prepared by such means against vaccinia virus could be used for the diagnosis of small-pox. It is of special interest in this connection to observe from the latest report of the Foot-and-Mouth Disease Research Committee that Professor Ciuca of Bucarest, working in London at the Lister Institute, has succeeded in applying the complement-fixation test to the diagnosis of infections by that virus, and that in this way he has been able to distinguish between the two different types of foot-and-mouth virus.

Recent developments, therefore, in the study of the filtrable viruses are of considerable promise, and their general tendency is to bring these infections more and more into line with those produced by the ordinary pathogenic bacteria.

YELLOW FEVER PROPHYLAXIS.

(Editorial, *British Med. Journ.*, 24th Nov., 1928, p. 947.)

INTEREST in yellow fever and its prophylaxis has been awakened by recent reports and correspondence in the *Times* referring to protective vaccine and its use in South America. The history of yellow fever investigations is both interesting and tragic, for others besides Adrian Stokes, Noguchi, and Young have lost their lives while probing into its secrets. The first definite advance in our knowledge of the etiology was made in 1901 by the American Commission, consisting of Reed, Carroll, and Agramonte, who, working at Quemados, proved that the vector was the mosquito *Stegomyia fasciata*, or, as it is now known, *Aedes argenteus*. It is true that many years before then both Beauprethuy and Finlay had suspected this mosquito, but the results of the American Commission placed the matter on a sure foundation. Two years later, at Rio de Janeiro, the observations were confirmed by the French Commission, composed of Marchoux, Salinbeni, and Simond. This newly acquired knowledge placed at the disposal of hygienists a method of prevention of which they availed themselves to the full in Central and South America, largely under the auspices of the Rockefeller Foundation. The yellow fever mosquito, which breeds in collections of water in and around houses, was relatively easy to attack. By stringent regulations and untiring inspection it was found possible to keep the mosquito index below the critical level, so that yellow fever as a terrible menace has ceased to exist in the great foci in the New World. There is, however, always the danger that it will appear where the anti-mosquito measures have not been applied, or should the energy of attack be abated. The disease is also endemic in West Africa, and from time to time occurs in serious epidemic form. Though some believed that the African disease was not yellow fever, there is no longer any doubt as to its nature.

It would appear that the application of the anti-mosquito measures which have proved so successful in America presents greater difficulties in West Africa, owing probably to the more primitive native population. This being so, it was all the more desirable that some other method of combating the disease should be discovered. Great hopes in this direction were raised by the announcement by Noguchi in 1919 that he had isolated the causative organism—*Leptospira icteroides*—which was allied to that which produces infectious jaundice or Weil's disease. With it a vaccine was prepared and an antiserum in horses, and these were issued for prevention and treatment. Though some observers appeared to confirm Noguchi's findings, there gradually accumulated evidence that Noguchi's leptospira was identical with that of Weil's disease. At this juncture, in 1925, the West African Yellow Fever Commission of the Rockefeller Foundation went to West Africa, where medical officers in the Colonial Service had repeatedly failed to recover a leptospira from cases of yellow fever. The late Adrian Stokes, who joined the Commission as a British representative, together with Bauer and Hudson, made the most important discovery that the disease was inoculable to Asiatic monkeys, particularly *Macacus rhesus*. In it the virus was easily maintained by direct inoculation of blood and tissues, or by mosquito transmission. This at once opened up a field for experimental investigation. It was shown that the disease was caused by a filtrable virus and not by a leptospira. Noguchi then, as an independent worker, went to West Africa from the Rockefeller Institute, and commenced his work at Accra at the laboratory of which W. A. Young, who had long experience of the disease in West Africa, was the director. As is well known, Noguchi and then Young fell victims to the infection. Though Noguchi's results have not yet been published, it is understood they are in agreement with those of the West African Yellow Fever Commission, which was working at Lagos.

Finally, A. W. Sellards of Harvard University went to Dakar, and with Mathis again confirmed the susceptibility of the Asiatic monkey. Sellards, as recorded in

the *British Medical Journal*,¹ on his return came to London and brought with him frozen virus, which, proving infective, enabled work to be carried on in this country. With this strain of virus Edward Hindle, the Beit Fellow in Tropical Medicine, carried out investigations in London at the Wellcome Bureau of Scientific Research. Applying to the experimental disease in monkeys the methods which had proved successful for the production of vaccines in the hands of Laidlaw and Dunkin in the case of dog distemper, and of Todd in the case of fowl plague, Hindle² found, that a phenol glycerin emulsion of the liver would confer on monkeys an absolute immunity against enormous doses of virulent virus. Meanwhile Aragao (1928), working at the Oswaldo Cruz Institute in Rio de Janeiro, demonstrated the susceptibility of the Asiatic monkey to the South American disease, and by a cross immunity test proved the identity of the American and West African viruses. Receiving Hindle's paper on the preparation of vaccine, Aragao repeated the observations with the American strain, and, after administering the vaccine to a number of laboratory workers with no untoward results, issued it for use in a small epidemic. In all, between three and four hundred people were vaccinated without accident, and, though no unwarranted conclusions are drawn, it is noted that none of the vaccinated contracted the disease. These encouraging results are being followed by the production of the vaccine on a larger scale, so that it will be available for use by the Public Health Department of Brazil.

One other aspect of the question deserves mention—namely, the protective action of immune serum of convalescents. It was shown by the French Commission in 1903 in the case of human beings, and by Stokes, Bauer, and Hudson in monkeys, that a comparatively small dose of serum from a recovered case of the disease would protect against infection. There is here a method of diagnosis in doubtful cases which may be of the greatest service. Furthermore, convalescent serum will confer an immediate immunity, and will have its uses when it is desired to immunize more rapidly than by vaccine. Hindle's vaccine, however, if it proves to be as effective in human beings as it is in monkeys, will be of the utmost value in the prevention of yellow fever, which hitherto has depended on a precarious and ceaseless vigil over the ubiquitous insect vector.

D. T. M. (BENGAL) PASS LIST 1929.

At the examination held in April 1929 at the Calcutta School of Tropical Medicine for the Diploma in Tropical Medicine of the Faculty of Tropical Medicine, Bengal, the following 34 out of 40 candidates were successful:—

Passed with distinction.

1. Raymond George Penington, M.B., B.S. (Melbourne University), Methodist Missionary Society of Australia, appointed to Australia Mandated Territory, New Guinea.

Passed.

- (Arranged in alphabetical order.)
2. Alexander Clement Abraham, L.M. & S. (Hyderabad University), Assistant Medical Officer, Osmania General Hospital, H. E. H. The Nizam's Department, Hyderabad Division.
3. Piyara Lal Bahl, M.B., B.S. (Punjab), Civil Assistant Surgeon, Burma Government.
4. Ramesh Chandra Basubharman, M.B. (Cal.), Health Officer, Behala Municipality, Behala, Calcutta.
5. Jogendranath Bhattacharyya, M.B. (Cal.), Bacteriologist, Bactro-Clinical Laboratory, Ltd., Calcutta.
6. Gopinath Chandra, M.B. (Cal.), Private Practitioner, Bengal.
7. Lieut.-Col. John Beresford Christian, M.R.C.S., L.R.C.P. (Lond.), I.M.S. (Retd.).
8. Jaganath Das, M.B. (Cal.), Civil Assistant Surgeon, Bihar and Orissa Government.
9. Monnoolall Dave, L.M.P. (C. P.), Assistant Medical Officer, C. P. Government.
10. Rasbehari Ghose, M.B. (Cal.), Private Practitioner, Bengal.
11. Narendra Nath Ghosh, M.B. (Cal.), Civil Assistant Surgeon, Bengal Government.
12. Adam Hamilton Harvie, M.B., Ch.B. (New Zealand University), Medical Missionary, Jagadhri Mission Hospital, Punjab.
13. Kodavayur Venkateswaran Raju Iyer, L.S.M.F. (Mad.), L.T.M. (Cal.), Assistant Surgeon, M. S. M. Railway.
14. Lancelot Richard Jones, L.M.F. (Bengal), Assistant Surgeon, Indian Military Department.
15. Anantha Vasudeva Kamath, M.B., B.S. (Mad.), Municipal Health Officer, Calicut, Madras.
16. Ragaretna Kanagasabapathy, M.B., B.S. (Mad.), District Health Officer, North Arcot, Madras.
17. Debendra Chandra Majumdar, M.M.F. (Bengal), Private Practitioner, Bengal.

takes place in all forms of free-living unicellular life. When the nutritional conditions are favourable, multiplication takes place asexually. When the environment becomes unfavourable, the organisms, after conjugation, assume the cystic or resting stages until conditions are again favourable for their sexual multiplication. When malarial gametocytes in the peripheral blood are increased in numbers, mosquitoes are more readily infectible.

(3) Gametocytes developed under quinine administration are viable, as shown by Darling, Ross, Barber, and Wenyon.

(4) Plasmochin is mainly effective against gametocytes, and it also has a marked action in clearing the schizonts of the tertian and quartan types of malaria from the peripheral blood. On the schizonts of the festivo-autumnal types, its action is negligible. It apparently does not prevent the development of black-water fever. Moreover, it is not as effective in preventing relapses when administered alone as it is in combination with quinine.

(5) It appears, from the few observations made by Dr. Barber and Mr. Kemp to have a toxic action on the crescents, as, after a few doses, mosquitoes feeding on these individuals do not become infected. This observation is exceedingly important, and if it is confirmed, plasmochin must be considered of paramount importance in malaria control.

(6) If given in too large a dosage, or over a too prolonged period of time, plasmochin may cause toxic symptoms. In a small percentage of cases there appears to be an idiosyncrasy for the drug, and this is the case also with some people when taking quinine. The daily dosage should not exceed 0.06 gramme, and this should not be continued over a period exceeding 6 days, unless the patient is under the closest daily observation. Apparently doses in excess of this are not more effective against the parasites.

(7) The toxic symptoms take the form of headaches, giddiness, gastric distress, cyanosis, etc., and the drug may cause death. Clinical findings at the onset of toxic symptoms are leucocytosis and erythrocyte degenerations.

(8) The administration of quinine in combination with plasmochin apparently prevents the development of toxic symptoms, and because of this and the therapeutic action of the two drugs on the different phases of the parasites, they should always be given in combination in order to get the best clinical results.

(9) Our experience indicates that for an adult the amount of quinine to be given daily in combination with plasmochin depends on the clinical symptoms. In chronic cases without acute symptoms, 1 gramme daily will suffice. In acute cases, from 2 to 3 grammes daily are necessary in order to obtain optimum results.

(10) In ambulatory cases not under daily supervision, the daily dosage of plasmochin should not exceed 0.04 gramme, in combination with 1 to 2 grammes of quinine, for a period not to exceed 6 days; or 0.06 gramme plasmochin, with the same dosage of quinine, over a period not to exceed 4 days. Whenever possible, all cases so treated should return for a re-examination within from 3 to 4 days after the course is completed; and if parasites are still present, a second course of treatment is indicated.

(11) All ambulatory cases should be warned that if they experience headaches, dizziness, or gastric distress or if blueness develops in the face or lips, the drug should be immediately suspended, and that they should report to the physician for further instructions.

(12) If, on a thick-film survey, the camp population should be heavily infected, 60 per cent. or over, blanket treatment of the whole population is recommended, and the course of treatment should be administered in accordance with the dosage referred to above. Within from 3 to 4 days after the last treatment is given, the camp should be resurveyed; and if any cases are still found positive, another similar course of treatment should be instituted. It has been demonstrated that the heavily-infected carriers (frequently without acute symptoms)

most readily infect mosquitoes, and that one heavily-infected mosquito may transmit malaria for 3 months at least. The importance of repeated surveys therefore, to discover and treat the carriers, cannot be too highly stressed, and it would be highly advantageous if this could be done during the dry season. This will prevent the high incidence of mosquito infection later on during the rainy season when conditions are more favourable for their multiplication.

Eight Years' Experience of Yatren in the Treatment of Amoebic and Bacillary Dysenteries and their Sequelæ.

By PROF. P. MUHLENS.

(Lecture delivered before the International Congress for Tropical Medicine and Hygiene at Cairo,

December, 15th to 22nd, 1928.)

The treatment of Amoebic Dysentery with Yatren must in every case be adapted to the individual patient. We meet with instances in which prompt amelioration follows the administration of the drug per os; others, again, react quickly and with certainty only to treatment by rectal injection; lastly, there are yet others in whom both methods have to be employed in combination if we are to attain speedy and complete cure. The method to be employed depends in the main upon the site of the amoebic ulcers: that is, whether the upper or the lower parts of the large intestine (e.g., in ulcerative colitis) or both are involved. Manson-Bahr and others maintain that in every case of chronic amoebic dysentery the condition must be accurately determined from the point of view of treatment, and that among matters to be attended to, examination of the stools, and a sigmoidoscopic examination are of paramount importance, particularly in severe cases. If the results of faecal examination are negative, we usually set up a provocative diarrhoea by stimulating the bowel with a dose of sodium or magnesium sulphate; by this means we often discover amœbæ which previously could not be found.

Anyone who does not try to determine accurately, prior to treatment, the chief site of the disease, that is, what part of the intestine is to be dealt with, and thereby direct the form of the treatment, is himself responsible for failure.

Failure can usually be explained by the fact that inadequate treatment has been given, owing in part to the fact that the diarrhoea which in certain subjects is produced by oral administration of Yatren had led to intermission of the course of treatment.

The non-toxicity of Yatren is generally acknowledged. Doses up to 12 gm. in the day have been prescribed and tolerated. Symptoms of intoxication following the administration have not been reported in the literature, although these are common in the case of emetine, etc.

In many individuals, especially those suffering from acute dysentery, the oral administration of Yatren may provoke a diarrhoea which, if excessive, is very debilitating, though it leads to no lasting mischief. For my own part, and others agree with me, I regard this as salutary in the therapeutic sense as causing a mechanical flushing of the bowel, provided that it does not become transformed into profuse diarrhoea in subjects already weakened by dysentery. In such cases, in the first place, oral administration of Yatren must obviously be prohibited, or the dose must be reduced.

It may be that those in whom Yatren provokes so profuse a diarrhoea are individuals with an idiosyncrasy for the iodine contained in Yatren.

The iodine is also probably the reason why the preparation is relatively expensive. In my opinion, if we take into account the shortening of the duration of treatment, of the loss of working time and the greater certainty of the results of treatment, the cost of a course of Yatren comes to less than treatment with emetine.

Furthermore, Yatren treatment has, since it was first introduced, already become considerably cheaper, in that the therapeutically active doses are now very definitely

lower as compared with those at first recommended by us, without any depreciation of the results produced.

Whereas Mühlens and Menk recommended at the beginning that for oral treatment of adults 4 pills, each of 0.25 grammes, should be given thrice daily, numerous later experiences have shown that in most cases successful results can be obtained with 2 pills three times a day, and it is best taken after food.

The scheme for a course of Yatren in pills is now as follows:—

First	day	1 pill	thrice in the day, after food.
Second	"	2 pills	" " " " " "
Third	"	2 "	" " " " " "
Fourth	"	2 "	" " " " " "
Fifth	"	2 "	" " " " " "

If this is well tolerated, then

Sixth	day	3 pills	thrice in a day, after food.
Seventh	"	3 "	" " " " " "

For after treatment, on every fifth, sixth and seventh day for 3 weeks, 2 pills should be taken thrice daily after food.

Thus, for a full course of 100 pills suffice; 25 gm. for a course per os.

In the very acute cases of amœbic dysentery many authorities give, at the start, a few emetine injections in addition to the Yatren. The writer does not find any need for emetine, and usually adds *opium* with the object of getting rid of or modifying the irritative symptoms resulting from the oral administration of the Yatren.

In other cases of early idiosyncrasy prompt habituation to Yatren can be obtained by beginning with small doses (0.1) and gradually increasing (two or three times 0.1 gramme and so on). Even in such cases treatment by rectal injections was practically always well tolerated.

Treatment by rectal injection is the method of choice, above all in cases of chronic amœbic dysentery as also in the sequelæ of the disease, in particular ulcerative colitis, membranous colitis, obstinate constipation, and also perhaps in sprue.

Further, failure has again and again occurred in treatment by rectal injection when too high concentrations (up to 10 per cent., Birt) have been employed, for they are strongly irritant and are not retained in the colon.

Yatren injections which do not remain for at least 6–10 hours and which, consequently, are not absorbed, do not attain their object. The infusions of Yatren must be preceded by a thorough cleansing of the bowel by means of a high washout enema.

"Yatren 105" puriss must be dissolved in water at 80°C. and should not be boiled.

Of recent years, it has been customary to administer the high injections in the following dilutions and amounts by means of a long intestinal tube; First day: 1 gramme Yatren in 200 c.c. water; second day: 2 grammes Yatren in 300 c.c. water; third day: 3 grammes Yatren in 400 c.c. water; fourth day: 3 grammes Yatren in 500 c.c. water; fifth day: 3 grammes Yatren in 600–800 c.c. water, provided that these larger quantities of 600–800 c.c. are retained for at least 6 hours; sixth day: 3 grammes Yatren in 600–800 c.c. water; seventh day: 3 grammes Yatren in 600–800 c.c. water.

If there is difficulty in retaining the injections we add to the Yatren solution 25–30 drops of Tr. opii or reduce the quantity of water, giving 3 grammes of the Yatren in 300–500 c.c. water. It is advisable to give the injections in the evening, so that absorption by the bowel can take place during the night. In this way the injection method, as also the treatment by Yatren in pill form, can be carried out in patients who are up and about during the day; in every case the subsequent treatment should be repetition of the injections every fifth, sixth and seventh days for a period of 3 weeks in concentrations of 2–3 grammes Yatren in 300–500 c.c. water. Stronger concentrations are rarely needed to bring about definite cure of long-standing cases.

The astonishingly high percentage of undoubted cures of amœbic dysentery by Yatren has up to now been attained by no other mode of treatment, assuming that these methods, or methods analogous to those which I

have detailed to-day, adapted to each individual case, have been strictly carried out.

The Use of Crude Oil as the Larvicide of Preference on the Isthmus.

By D. P. CURRY, M.D.

(Proceedings of the Med. Assoc. of the Isthmian Canal Zone, 1927, Vol. XV, p. 39.)

IN spite of the ever-increasing amount of drainage for the prevention of mosquito breeding in the Canal Zone, there yet remains in those places where it is impracticable to eliminate the water in which mosquito breeding may occur, a need for a larvicide that is safe, efficient, cheap, and easily applied. At one time much experimenting was done here to determine what substance was the best for that purpose, with the result that preference was given to two agents—the crude fuel oil of commerce, and a cheap resin-soap solution of crude carbolic acid. Because of rising cost of the ingredients of the carbolic acid solution, and of better methods of applying the crude oil, the use of the latter has for the past 6 or 7 years entirely superseded the use of the more expensive (and really less efficient) carbolic acid solution.

Fuel oil, as used for mosquito control on the Isthmus, is brought here in tankers from the oil fields of North or South America. From the ships it is pumped ashore into large steel or concrete reservoirs, and from these the oil is distributed by pumping through pipe lines to the small Health Department supply tanks located miles away on the lakeside, as conveniently as possible to the points of application. Delivered at the water's edge, ready to be drawn by gravity into the boat tank, the cost of the oil at the present time is \$1.35 (Rs. 4) per barrel of 42 gallons, or less than 3½ cents (2 annas) a gallon. Three men are required for its application; one to row or pole the boat along, one to work the pump, and one to handle the long pipe ending in a spray nozzle. The hot oil can be sprayed on the shore line as fast as the boat can be propelled and surface filming is positive and complete. Wind action and wavelets carry the oil into every nook and cranny, even to a considerable distance from the point of application. Fairly dense grass and other vegetation does not offer a serious bar to success. Inspection follows every oiling to determine if it has been done thoroughly, and if it is effective in destroying the larvae. The results apparently could not be cheapened or improved by any other method that is as efficacious.

Elsewhere than in the lake areas, mosquito breeding is controlled chiefly by training of streams and by draining and filling. Some oiling is of course done in the open streams and ditches, especially in the dry season or at times of slight precipitation. What were formerly known as "oiling gangs" are now better described as "maintenance gangs," the use of oil becoming less and less each year. Such gangs now carry spades and rakes, as well as oil, and are instructed to eliminate by drainage or filling whenever possible, every bit of water that may prove a potential breeding-place within a controlled area.

The results of our methods of control and of the more recent extension of sanitation to greater distances from protected communities than was formerly the case, are shown in other ways than by malaria rates alone. Frequent observations are made both at nightfall and at dawn, with a view to determining what mosquitoes are on the wing. Whereas in earlier years such efforts usually resulted in catching many of the malaria-carrying species within the town sites, for the past two or three seasons such mosquitoes are only rarely so caught, and places where formerly they might always be found are now practically free from them. Of course this has not been a sudden occurrence following any particular year's work but really is the cumulative result of many years of progressive effort. In fact, were it not for the presence on the Isthmus in large numbers of two harmless, though very annoying species of mosquitoes, the public would hardly realize now that a mosquito problem exists. These two mosquitoes are *Aedes taeniorhynchus*,

the banded salt-marsh mosquito, and *Mansania titillans*, a mosquito of very similar appearance on casual examination but of very different breeding habits. Both are voracious biters and both fly long distances from their breeding-places.

Studies in Malaria, with Special Reference to Treatment.

Part XI.

THE CINCHONA ALKALOIDS IN THE TREATMENT OF BENIGN TERTIAN MALARIA.

By J. A. SINTON,

MAJOR, I.M.S.,

and

W. BIRD,

MAJOR, R.A.M.C.

(The Indian Journ. Med. Res., January, 1929, p. 725.)

ALTHOUGH much scientific work has been done on the effects of the different cinchona alkaloids in the treatment of benign tertian malaria, most of it has had reference to the production of clinical cures and few such experiments have been made, in which the patients were observed by systematic blood examinations for the occurrence of relapses after the termination of all treatment. The methods considered necessary for testing the effects of any treatment in the production of a permanent cure in malaria have been detailed in another paper of this series.

The researches which have been carried out by different workers in recent years would indicate that, in as far as the reduction of fever and the rate of disappearance of parasites from the peripheral blood is concerned, the four common crystallizable alkaloids of cinchona bark, namely, quinine, quinidine, cinchonine and cinchonidine, have almost an equal value when administered in therapeutic doses to patients suffering from benign tertian malaria. If these same relative values should be found to exist when the alkaloids are tested for the production of a permanent cure of the disease, it would have a very important influence upon the present policy of cinchona cultivation. Quinine, however, still seems to be the drug of preference in the treatment of the malignant tertian type of the disease.

The results recorded in this paper have been obtained during 5 years of work on the anti-relapse treatment of malaria, and during that time over 1,300 patients suffering from benign tertian malaria have been treated with the different cinchona alkaloids.

Summary of Results.

It is seen from the figures given in the table that the results obtained after the treatment of chronic benign tertian malaria by quinine, cinchonine and cinchonidine were almost the same. It would, therefore, seem that

in therapeutic doses these three drugs have an almost equal value. It must, however, be noted that the dosage of quinine was greater than that of the other two alkaloids. Whether the latter alkaloids would give better results, if they could be tolerated when administered in the same doses of quinine was not determined.

Quinidine was found to give a distinctly higher relapse rate than the other alkaloids tested. There was no evidence that it had a greater curative action in infections with *P. vivax* than had quinine.

Cinchona febrifuge treatment gave a slightly higher average rate than did quinine, cinchonine and cinchonidine, but showed a better result than quinidine.

Comparison of the Relapse Rates in Fresh and Chronic Infections.

The opinion formed by many workers during the Great War was that, in fresh infections with *P. vivax*, a much smaller percentage of relapses developed after treatment than in the case of the chronic relapsing ones. On the other hand, some workers, as Acton, Curjel and Dewey (1921), thought that fresh infections were not more easily cured than chronic ones.

It has been the experience of most workers in the tropics that few patients, unless subject to discipline, will conscientiously carry out the long courses of quinine treatment usually recommended for the cure of malaria. Even patients under strict discipline make efforts, sometimes successful, to escape from the tedium of this form of treatment. It is also extremely common, especially among uneducated persons, for a patient to take treatment only while clinical symptoms are present and then to abandon all treatment until a relapse occurs. Yet, in spite of this, very many patients treated for primary infections with *P. vivax* seem to be permanently cured by such curtailed courses, in the absence of reinfection. Such cures probably represent that proportion of patients whom it has been found possible to cure by short courses of quinine after experimentally-induced infections. If a considerable proportion of patients suffering from primary attacks were not cured by such short or incomplete courses, and relapsed subsequently, the number of malarial patients in tropical countries would be even greater than at present.

Although the view that fresh infections were more easily cured was believed by many workers, yet little scientific proof was forthcoming, because, until the introduction of malaria in the treatment of mental disease, almost all the systematically controlled researches into the anti-relapse value of the cinchona alkaloids had been conducted with chronic relapsing infections. This was necessary on account of the great difficulty in obtaining fresh infections in sufficient numbers under conditions suitable for carrying out careful work in the absence of reinfection.

As can be seen from the results obtained in this paper, such chronic infections are not comparable to fresh infections in their reaction to treatment. The former probably represent those patients who were inadequately

TABLE.

Alkaloid used.	Total patients.	Number lost sight of.	Number not relapsing.	Number of relapses.	PERCENTAGE OF RELAPSES.				
					Observed.	Possible maximum.	Observed minimum.	Average.	Deviation from average.
Quinine ..	667	66	184	417	69·4	72·4	62·5	68·0	— 3·2
Quinidine ..	208	14	30	164	84·5	33·6	78·8	83·0	+11·8
Cinchonine ..	72	3	22	47	68·1	69·4	65·3	67·6	— 3·6
Cinchonidine ..	107	24	23	60	72·3	78·5	56·0	68·7	— 2·5
Cinchona febrifuge	110	25	19	66	77·6	82·7	60·0	73·1	+ 1·9
TOTAL ..	1,164	132	278	754	73·0	76·1	64·7	71·2	...

treated during their primary infections or represent that minority which it has been found in experimental malaria are not easily cured of the disease.

James (1924), Manson-Bahr (1924) and Yorke (1925) all think that the difference in the susceptibility of induced malaria to quinine treatment has something to do with the fact that one is dealing with primary infections instead of with chronic relapses.

Of 25 known primary infections with *P. vivax* contracted in nature and treated with quinine for 8 weeks, only 1 or 4 per cent. relapsed. Among 154 patients, many of whom were fresh infections, the relapse rate due to *P. vivax* was only about 30 per cent. after a short course of quinine treatment (4 to 7 days), in spite of the fact that some of the relapses recorded may have been reinfections. The relapse rate was about 14 per cent. amongst 44 patients treated under similar conditions but observed mainly by clinical methods.

If all these cases are grouped together, although not all fresh infections, there is a total of 251 patients with a relapse rate of about 24 per cent. This figure is very close to the 25 per cent. obtained by James (1926) following the treatment of patients infected by mosquito bites experimentally.

On the other hand the relapse rate among 667 chronic infections treated with quinine averaged 68.0 per cent. and for 1,164 patients treated by different cinchona alkaloids was 71.2 per cent. These results are very similar to those recorded in the researches after the War.

These figures help to confirm the opinion of clinicians, strengthened by the results of the treatment of induced malaria, that the majority of fresh infections contracted in nature are more easily cured than are chronic relapsing ones.

Conclusions.

Under the conditions of our tests and with the dosage of cinchona alkaloids used, the following conclusions were arrived at regarding the relapse rates after the treatment of infections due to *P. vivax*.

(1) The percentage of relapses in a population suffering from fresh infections with *P. vivax* is much lower than the percentage among a population composed of chronic relapsing infections only.

(2) The quinine and alkali treatment seems to be more efficacious than quinine alone in curing fresh infections, but the results in chronic infections showed no very marked benefit.

(3) The four chief crystallizable alkaloids of cinchona bark—quinine, quinidine, cinchonine and cinchonidine—showed almost an equal value in preventing relapse in chronic infections. Quinidine gave the worst result.

(4) No evidence was found to confirm the assertion that quinidine was more effective than the other alkaloids in the treatment of infections with *P. vivax*.

(5) Cinchona febrifuge has a value which, for most practical purposes, seems equal to that of the pure alkaloids in the treatment of chronic infections.

APPENDIX A.

Prescriptions of Mixtures used in Treatment.

- | | |
|--|-------------------------------------|
| (1) Quinine sulphate .. | .. grains 10. |
| Acid sulphuric dil. .. | .. minims 10 |
| Water to .. | .. ounce 1. |
| (2) Similar to No. 1 but magnesium sulphate. | 60 grains, was added to each ounce. |
| (3) Quinine sulphate .. | .. grains 10. |
| Acid citrici .. | .. grains 25. |
| Magnesium sulphate .. | .. grains 60. |
| Water to .. | .. ounce 1. |
| (4) Similar to No. 3, but without magnesium sulphate, and with 12 grains of quinine to each ounce. | |
| (5) Quinidine sulphate .. | .. grains 10. |
| Acid sulphuric dil. .. | .. minims 10. |
| Water to .. | .. ounce 1. |
| (6) Quinidine sulphate .. | .. grains 10. |
| Acid citrici .. | .. grains 25. |
| Magnesium sulphate .. | .. grains 60. |
| Water to .. | .. ounce 1. |

(7) Similar to No. 5 but quinidine sulphate was replaced by cinchonine sulphate or cinchonidine sulphate in the same dosage.

(8) The same mixture as in No. 5 except that quinidine was replaced by cinchona febrifuge in the same amounts. The mixture was strained through lint to obtain a nicer preparation.

The following mixture was also given before each of the mixtures shown above in some instances.

Sodium bicarbonate grains 90.
Sodium citrate grains 45.
Calcium chloride grains 5.
Water to ounces 2.

Some of the mixtures used contained various flavouring materials to disguise the taste.

Swimming Baths.

(Abstracted from *The Medical Press*,

January 16th, 1929, p. 49.)

OFFICIAL attention has been directed to the dangers arising from the public swimming baths in Paris, these being subject to regulations requiring frequent renewal of the water and cleansing of the bath. The habit of afternoon bathing has much increased of late, and many of the large establishments of various kinds have provided baths in which, after taking a plunge, the bather sits in bathing costume in the adjoining café and partakes of refreshment. Some of these baths are said to be used by from 1,200 to 1,400 persons daily, though they contain only 700 cubic metres of river water, renewed but once a week. Under such conditions various diseases may be contracted, such as conjunctivitis, inflammation of the throat, nasal fossæ, and Eustachian tubes, and gastro-intestinal disorders; for bacteriological analysis of the water shows that it rapidly becomes contaminated with innumerable species of micro-organisms. A rough method of recognising the degree of contamination, as used in Paris, is the filtration of five litres of water under pressure through discs of white flannel, the foreign matter retained being collected and analysed. The health authorities may order the more frequent renewal of the bath water, or its filtration or sterilisation by Javelle liquid (hypochlorites). The method of examination adopted by the London County Council consists of counts per cubic centimetre of the bacterial colonies, obtained after forty-eight hours' plate culture on agar at 37°C. from 0.1 to 0.5 cubic centimetres of the water; and includes tests for the presence of *Bacillus coli communis* in samples of from 1 c.c. to 10 c.c. The standard adopted by the Bathing Committee of the American Public Health Association requires that: (a) not more than 1,000 organisms in twenty-four hours' growth at 37°C. shall be found in more than 10 per cent. of samples; (b) not more than two out of five samples of 10 c.c. on the same day shall show the presence of *B. coli*. The swimming baths within the jurisdiction of the London County Council appear to have answered adequately to the required tests, but without the reports of the various local authorities of the large provincial cities and towns there is no means of gauging the efficiency of the supervision exercised by them. The matter is one to which their careful attention should be directed.

Ophthalmological Notes.

(Abstracts from *American Journ. of Ophthalmology*, December, 1928, Vol. II, p. 1007.)

Angelucci, A. Autohemotherapy and iontophoresis in ophthalmology. *Arch. di Ottal.*, 1926, Vol. 33, Oct., pp. 439-463.

In trachoma the author uses parenteral injections of five to ten cubic centimetres whole blood with one-half to one cubic centimetre or serum given subconjunctivally. He reports good results, especially in cases with corneal complications. In incipient cataract he claims good results from iontophoresis with an iodide solution.

Blatt, Nicholas. Interference in ocular diseases. *Gracfe's Arch.*, 1928, Vol. 120, p. 335.

As examples of the well-known beneficial action of intercurrent disease, the author gives in brief the history of a number of his cases with primary ophthalmic disease affected favourably by other disorders. In three cases of parenchymatous keratitis, one was much improved by an attack of scarlet fever, another by diphtheria, and a third through angina and tonsillitis. An attack of phlegmon of the eyelids apparently cured a case of long-standing chronic catarrhal conjunctivitis, the onset of acute purulent conjunctivitis cured another, and influenza a third case of chronic catarrhal conjunctivitis. An attack of scarlet fever stopped the activity of a herpes corneæ, anthrax that of an ulcerative blepharitis, and gonorrhœal corneal ulcer that of a syphilitic uveitis. Among seventeen cases of tabetic optic atrophy treated with malaria, according to Wagner-Jauregg, in four the process was checked and the vision brought to a standstill.

Braunstein, N. Treatment of eye diseases by means of ultra-violet rays. *Zeit. f. Augenh.*, 1928, Vol. 65, July, p. 232.

A BRIEF report of treatment of nineteen cases of ulcer serpens, eleven of tuberculosis, fifteen of phlyctenular conjunctivitis, six of herpes corneæ and four of old corneal opacities. In all these classes of case the author notes striking improvement as a result of this form of treatment which is neither dangerous nor difficult.

Demaria, E. B. Treatment of tuberculous lesions of the eye with minute doses of tuberculin. *Arch. de Oft. de Buenos Aires*, August, 1928, Vol. 3, p. 539.

THE author reviews the various applications of tuberculin, from Koch up to the present, along with theoretical conceptions upon which changes in the original technique are based. The method he employs at present was instituted by Viton of Buenos Aires, and was presented during 1923 in a book entitled *Tuberculin Therapy*. The minutest doses of tuberculin are recommended both for diagnostic and therapeutic purposes.

A general resume of the Viton method of employing tuberculin in contrast with that of Koch is distinctly in favour of the former as to the patient's general condition. The Viton technique uses four strengths in which the tuberculin is diluted with physiological saline solution up to a strength of one part to 9, 10, 11, and 12 zeroes respectively. Where the patient is very susceptible to its effects, this is carried still farther, even up to 25 zeroes.

Elkes, C. Besredka's bacteria-free filtrates and their therapeutic use in diseases of the eye. *Zeit. f. Augenh.*, 1928, Vol. 65, June, p. 135.

If ten-day broth cultures of staphylococcus are filtered and sterilized by heat, one obtains a culture medium in which other organisms grow freely but in which staphylococcus grows poorly or not at all. To explain this an antiviral, thermostable in contrast to the thermolability of the virus, is postulated, by analogy with anti-ferments which develop in certain cells, as for instance leucocytes. In a small series of cases—hordeolum, chronic dacryo-cystitis, conjunctivitis—rapid healing followed repeated application of antiviral to the mucous membrane of the conjunctival or lacrimal sac.

Tsykulyenko, K. J. Omitting the eye dressing in post-operative care. *Russkii Ophth. Jour.*, 1928, August, pp. 263-266.

THE author is in favour of the "open" treatment of operative cases. In sixty-seven cases of intraocular operation, of which twenty-eight were cataract extractions, dressings were completely omitted in the post-operative period. A wire mask similar to Fuchs's was used for the protection of the operated eye. No ill results followed.

Bolkmann, Gunther. Treatment of ocular diseases with a new non-specific fever-producing substance (pyrifer). *Zeit. f. Augenh.*, 1928, Vol. 65, May, p. 10.

PYRIFER consists of protein from a non-pathogenic bacterium, and was first proposed as a harmless substitute for the malaria treatment of parasyphilis. The author used it in acute infections of the cornea and uvea, in injuries, and in two cases of syphilis and parasyphilis of the eye.

He found it effective in cases where milk was effective, namely, in fresh inflammatory lesions, and it was sometimes effective after milk reaction had become exhausted. The reaction was severer and more unpleasant than after milk. The remedy was not tried in gonorrhœal infections.

Professional Etiquette.

(*The Lancet*, January 19th, 1929, Vol. CCXVI, p. 145.)

THE recently published rulings of the General Council of the Bar upon doubtful points of etiquette and conduct are of interest to other professions. Two points in connection with advertisement are specially dealt with. A barrister inquires if there is any objection to his broadcasting a short course of popular lectures on general topics of law with the usual insertion of his name and short particulars in the *Radio Times*, and the description "barrister-at-law." He also asks—with a courage which will shock the older generation of barristers strictly trained in circuit discipline—whether his photograph may appear in the B. B. C.'s quarterly "Talks and Lectures." The General Council of the Bar answers that he may broadcast the lectures as given by a "barrister-at-law," but that his name, address, and photograph must not appear. Thus novel wireless developments have raised an old issue afresh; few barristers can have had any doubt as to how the Council would decide. The decision is in keeping with the long-established principle forbidding a member of the Bar to advertise himself by articles under his own name on legal topics in popular journals. Specialist articles in specialist publications like the *Lancet Quarterly Review* are, of course, on an entirely different footing. The second point of this nature dealt with by the Bar Council's Annual Statement for 1928 is the answering of legal questions by barristers in newspapers. Here the Council republishes a former "warning notice" which it has caused to be displayed also on the screens of the libraries and common rooms of the Inns of Court during the past year. The notice observes that the Council's attention has been called to the increasing practice of legal journals advising or professing to advise their subscribers on points of law arising in actual practice. It mentions a recent instance where a firm of publishers has offered free advice on conveyancing matters to all subscribers to one of its publications. The Council has no means of knowing whether such advice is supplied by members of the Bar, but it believes that in some cases the advice is represented to the client as being "counsel's opinion." It reaffirms its former rulings and declares unequivocally that it is contrary to professional etiquette for a barrister to answer legal questions in newspapers or periodicals, whether for a salary or at ordinary legal remuneration: (1) where his name is directly or indirectly disclosed or liable to be disclosed, or (2) where the questions answered have reference to concrete cases which have actually arisen or are likely to arise for practical decision. A barrister inquired if the Council would give any further guidance

by defining more narrowly the reference to "a particular question likely to arise for practical decision." Not to be drawn into hypothetical cases, the Council replied that it was a matter for the discretion of the barrister himself. That final answer counts for much in these cases of doubt. If a professional man knows that certain forms of self-advertisement are illegitimate and contrary to the accepted traditions of his fellow-practitioners he can refrain from treading close to the borderline. Every profession has its members who sail close to the wind; their colleagues know them and form their own opinion. In this matter of advising on technical questions in journals the legal profession has probably had some increased demand or opportunity lately in view of the revolution in the law of conveyancing and real property which has sent back to school again many men of long experience and adequate instruction in the older law. The medical profession is here not quite in the same position as the legal. Advice upon health is a personal matter; the patient must be seen by the practitioner, whereas in many cases a barrister might be able to give an opinion—upon the interpretation of a clause, for instance, or upon the inference to be drawn from correspondence—without an interview. Moreover, questions of health are usually more urgent than questions of legal rights; a patient may be unwilling to wait a week for the printed reply. In other respects there is no great difference between the official standards of the Bar Council and the General Medical Council. In both professions there will be members, junior as well as senior, who are a law unto themselves. The standards cannot be upheld unless they are supported by the general approval of the rank and file. If they have that approval they are entitled to the loyal obedience of all.

Influenza.

(Abstracted from *The Medical Press*,
January 23rd, 1929, p. 68.)

DURING the last few weeks a very rapid spread of influenza was reported from the United States of America and Canada, suggesting that a European visitation is probable, and a world pandemic by no means impossible. Previous pandemics have occurred in 1803, 1833, 1847, 1890, and 1918-19, the last being answerable for the greatest mortality ever recorded for any epidemic disease in England since registration commenced, and for more deaths and disablement than the Great War. In June, 1918, influenza made its appearance, and, continuing through July, was followed after a short interval by a second wave of prevalence in the three last months of the year, and by a third in February and March, 1919. The summer epidemic was comparatively mild—the mortality was just over 29 per 100,000 population—but the subsequent waves were characterised by more severe symptoms and a tendency to pulmonary complications, and the mortality rose to 269 per 100,000 in October-December, 1918, falling to 104 per 100,000 in February-April, 1919. In some of the great towns of England the death-rate exceeded 400 per 100,000; from June, 1918 to May, 1919, the deaths in England and Wales numbered 151,446, and in India alone more than six millions perished. The predilection was for middle life rather than for the extremes of age; the largest proportion of deaths occurred in persons under forty-five years, a characteristic which has not been observed since.

The usual complications of influenza are pulmonary or cardiac, pneumonia being one of the commonest, and to these death is generally due; but in these fatal cases the intervention of some microbe, not specifically associated with influenza, is usually demonstrable, the invasion of which is favoured by the already lowered resistance caused by the infection. Theories as to the periodicity of epidemic influenza postulate, in one case an interval of thirty-three weeks (Brownlee), or in another (Spear) a recrudescence at equal intervals before and after the thirty-fifth week of the year; but neither is invariably true nor enables the degree of severity to be foretold.

Influenza is already among us again—it is useful to remember its former ravages—and it is the duty of the

public authorities to take steps to lessen the opportunities of infection, to assist in treatment and nursing, and to mitigate the severity of the hardships arising from the simultaneous attack of various members of the same household. In like measure it is the interest of the individual to take every precaution against infection, and if he be already infected, it is incumbent upon him to prevent himself from infecting others by unguarded coughing and sneezing.

Emil Von Behring.

MARCH 15th, 1929, was the 75th anniversary of the birth of Emil von Behring. His work as a pioneer on serum therapy is well known, but a short note on his life and work may perhaps prove of interest.

Son of a large family—the father was a teacher in Hainsdorf near Deutsch-Eylau, Western Prussia, he learned early the hardship of earning his living. With 12 children the father saw no way to afford a high-school education for this boy, who yet early showed a liking for medicine.

His intelligence, however, won him the favour of his teachers and they procured him a scholarship at the high-schools.

At 20 years of age, he entered the Military Medical Academy at Berlin, which he left at the age of 26 years after having been admitted a doctor.

He now joined the German Army as a military surgeon. He showed a strong inclination for scientific research and a surprising ability for observation.

In 1882 he formulated an entirely new theory of the action of bactericidal mediums and laid the foundations of his subsequent pioneer work on blood-serum therapy.

He gave up his military career, became a scientist, carried through his experiments under trying economic conditions and finally published in the winter 1890 his epoch-making discoveries in blood-serum therapy, namely, that the blood-serum of animals recovered from a disease has the power to cure another animal affected by the same disease.

The practical application of this theory led him to the discovery of anti-diphtheria serum.

The rate of diphtheria casualties fell wherever physicians applied diphtheria curative serum, humanity was freed from a most cruel scourge that hitherto had decimated its children.

Here it should be mentioned also, that already in 1890 Behring, in collaboration with Kitasato, had prepared anti-tetanic curative serum, the value of which equalled that of the anti-diphtheria serum.

Besides these problems he devoted a considerable part of his life to the study of tuberculosis.

Numerous honours were bestowed upon him. The "Institut de France" and the "French Academie de Medecine" in 1890 presented with him honoraria of 50,000 and 25,000 frs. The French Government followed with the appointment as officer of the Legion of Honour. England distinguished him by the honorary membership of the "Royal Institute of Public Health," the latter bestowing upon him the "Harben medal." The King of Italy decorated him with the Cross of the Commander of the Order of the Italian Crown. Besides other important Italian scientific corporations, the "Reale Societa Italiana" made him an honorary member. In the United States of America he became honorary member of the "American Academy of Arts and Science" and the "New York Academy of Medicine." Austria-Hungaria, Russia, Turkey, Roumania, Sweden, Belgium and other nations made him an honorary member of their most distinguished scientific societies. The Universities of Athens and Mexico conferred upon him the degree of "doctor honoris causa." The Sultan of Turkey presented him with the order of Medjidiji, 1st class, and Roumania with that of Meritul Sanitar, 1st class. In 1901 he was the first recipient of the Nobel Prize.

In recognition of his scientific achievements the German Emperor raised him to the hereditary peerage. In 1903 von Behring was nominated "Wirklicher Geheimer Rat" with the title "Excellency."

In March 1917 he died at the much-too-early age of 63 and his remains were buried in a mausoleum near Marburg-Lahn, surrounded by a peaceful landscape and close to his creation, the Behringwerke.

Reviews.

ASPECTS OF AGE, LIFE, AND DISEASE.—By Sir Humphry Rolleston, Bart., K.C.B., M.D., Hon. D.Sc., D.C.L., LL.D., Regius Professor of Physic in the University of Cambridge. London: Kegan Paul, Trench, Trubner and Co., Ltd., 1928. (The Anglo-French Library of Medical and Biological Science.) Pp. 304. Price, 10s. 6d. net.

We wish that we could convey to our readers something of the delightful humour and yet sound professional advice conveyed to the medical profession in this charming collection of essays and addresses by one of its most outstanding and honoured exponents; the best equipment for a successful general practitioner, we are told, consists of "one-quarter *savoir*, and three-quarters *savoir-faire*." He will find the "three-quarters *savoir-faire*" in this volume. Further, it is studded with delightful literary and classical quotations, apposite, entertaining, and wholly to the point. We read through the volume in an evening with intense enjoyment, and we can recommend to medical men in search of literature for a leisure hour no finer fund of common sense and humour. It deserves to become a classic.

The essays and addresses included deal with no less than thirteen different subjects and aspects of medical interest; they cover a very wide field, and are consequently difficult to review. The first concerns old age and longevity. And here we are told the authentic story of old Thomas Parr of Winton, Shropshire, who died at the age of 152 years. He first married at the age of 88; then begat two children; then was

involved in matrimonial complications—for which he had to do penance in his village in a white sheet—at the age of 105. At the age of 122 he married again, a second time, a widow. In 1635, at the age of 152, he was sent for by King Charles I who desired to see this ancient of days in person. This proved to be the old man's undoing; he lodged in London with the servants of the Earl of Arundel, and died of a plethora from drinking wine. William Harvey, the discoverer of the circulation of the blood, performed the post-mortem examination and reported that the organs were essentially healthy and that no lesion could be discovered other than the plethora induced by the rich living in London to which the deceased was unaccustomed. Truly, a wonderful life, lived out literally to the full. Unfortunately Thomas Parr did not survive to the present age to be the counsellor of the youth and age of to-day; he would have been a wonderful asset to a British Cabinet. In passing, we need not dwell on the cases of a Hungarian couple, Johan Roven and his wife Sarah, whose married life lasted for 147 years, and who died at the ages of 172 and 164 years respectively; had they been living to-day, surely they would have been appointed as special consultants to the Divorce Court.

The author gives a most interesting summary of the factors affecting longevity, as well of the fallacies in assessing the true age. In addition to environmental and personal factors, heredity is of great importance, and the upshot of the matter is that a child should exercise the utmost care in selecting his parents and grandparents. In spite of Maeterlinck's wonderful vista of future generations in his *Bluebird*, we fear that the advice is to-day impracticable! People in the country in general live longer than those in towns, whilst worry is the chief enemy of old age; "fresh air, meagre food, freedom from care" constitute the essential factors in a healthy and vigorous old age.

Chapter II deals with historical instances of disease in celebrated persons, and their effects on history. The "glory which was Greece" was extirpated by malaria; whilst in the Middle Ages many cases of natural sudden death were probably wrongly attributed to poisoning. Is genius allied to mental instability, or otherwise? Was eyestrain the cause for the sudden discontinuance of the fascinating diary of Samuel Pepys? What was Napoleon's pituitary condition, and was his failure at Waterloo due to *petit mal*, on-coming gastric carcinoma, or (to ascribe a more vulgar cause) an attack of inflamed piles? What is the value of the *spes phthisica* in literature, art, and music? Was the Franco-Prussian war of 1870 precipitated by the fact that Napoleon III suffered from vesical calculus? One is driven to wonder what was the exact condition of Cleopatra's endocrine glands, and how any abnormality in them might have affected the course of history. But enough has been said to show the fascination of such studies in historical medical lore.

Chapter III deals with diseases as described by medical men who themselves suffered from them, again a field rich in interest and speculation. We believe that it was Sir Thomas Sydenham who wrote that he was, as far as he knew, the first patient to be attended by ten doctors who had survived,—a case not entirely dissimilar from that of the recent illness of H. M. the King-Emperor. Here Bright, Addison, and Hodgkin—the great triumvirate of Guy's Hospital—are the most outstanding names. Mark's study of acromegaly was the result of looking into his own facies for 15 or 20 years every day when he shaved or brushed his hair. Migraine has been described by many medical sufferers from the disease; asthma by others, including laboratory workers who have striven to solve the perplexing ætiology of this symptom-complex. Gout is the bane of the medical profession, the most notable sufferer being Thomas Sydenham, whilst Benjamin Franklin also wrote a thesis on the same subject from the point of view of a patient. (Unfortunately Sir Humphry Rolleston does not describe modern surgery from the medical patient's point of view, but the reviewer—

writing from personal experience—can inform him that such a section is badly wanted in this chapter; it would teach the young surgeon a very great deal if he had to undergo a major operation on his own person!) Sir James Mackenzie, who died of angina pectoris, is an example of a man who devoted the whole of his long professional life to studies on the action of the heart. Tuberculosis, of course, has been described by a considerable number of medical sufferers from the disease. Rupture of the tendo Achillis led Alexander Munro of Edinburgh to record his accident, and a similar condition, sustained whilst dancing, led John Hunter in 1768 to carry out experiments on dogs with regard to the healing properties of this tendon: (the results of these experiments should certainly be republished at the present day—or, possibly, newer experiments might be instituted to conform to more recent methods of dancing, and injuries to the extensor as well as flexor tendons of the foot studied). Percivall Pott's fracture, due to a fall from a horse, has kept his name for ever memorable in surgical literature.

"Clinical variations in disease from the historical point of view," constitutes one of the most important and thoughtful essays in the volume. Here this important subject is well dealt with, but in all too brief a fashion; it is one on which much more information should be collated from a wide variety of sources of information. (A special feature of the book is the inclusion at the end of each chapter of chosen selected bibliographies; these will be of special value to serious students who wish to follow up the literature on the subjects concerned.)

Chapter V deals with the same subject, "changes in the clinical aspects of disease" from the historical point of view. Scarlet fever is probably the most typical instance; once a most dread disease, it has now become almost innocuous. A second is alastrim—if this is, indeed, but a mild variant of small-pox. On the other hand, readers of this journal will recall the terrible experience of India with regard to influenza in 1918-19. Beginning in August 1918, as a mild epidemic infection in Bombay and the adjacent districts, about six weeks later it assumed wide prevalence and an intensely fatal form: it swept the peninsula of India for some twenty-four months and caused some seven million deaths, often affecting villages situated in remote jungles or hill ranges, almost cut off from human intercourse. The study of this problem is one which demands careful attention. At the moment of writing (February, 1929), Europe is again in the grip of epidemic influenza; will this mean a new and terrible pandemic in India this year, or will the hot weather of 1929, with its high atmospheric temperature prevent the widespread dissemination of the disease? In India to-day, we are forewarned, but we are not forearmed. The different virulence of syphilis in different communities is again a subject of comment in the book, and has been much commented on in medical journals in recent years.

Chapter VI, "Medical Aspects of Holidays"—is one which both the layman and the medical man should read. Some people never take holidays, and seem to get on very well without them; others take too strenuous holidays, and subsequently wish that they had not: a third group—and this especially applies to medical men—are too wont to take a busman's holiday, and spend it in medical study at some foreign centre. We agree wholeheartedly with the author that the weekly Sabbath should be observed by the doctor as a complete holiday; let him disconnect his telephone on this one day of the week, close his consulting room, and open no letters or journals. A sea-voyage is almost the ideal form of holiday, for it enforces the conditions of absolute rest, freedom from professional worries, and absence of correspondence which should accompany a real holiday; but let the doctor travel as "Mr. ", and never "Dr. "; or he may be worried to death on board ship.

The medical aspects of tobacco come for consideration in chapter VII. We have already abstracted this

address *in extenso**, so need not return to the subject again. Those of us addicted to the noxious weed will do Sir Humphry Rolleston the justice of saying that we are not really terrified after reading his address upon the subject. We know that it affects the nervous system, the heart, and may induce amblyopia; but we also know that it conduces to mental satisfaction, to a calm and contented mind, that no after-dinner speeches could be made without it, and that to-day women are almost as much addicted to smoking as men. It must be left for future ages to decide whether smoking will have that terribly deleterious effect upon the race that the "antis" in America, having (?) abolished alcohol, now predict for the effects of tobacco. To quote our author—

"To smoke or not to smoke, that is the question,
Whether a mild cigar assists digestion,
Or whether it begets a kind of quaintness."

Anyhow it is an ancient rite, not unassociated with the "pipe of peace," and goodwill among men. (Again, the reader who is interested, will here find a useful bibliography to the subject under discussion.)

"Professional careers," (chapter VIII), is an address to medical students at King's College Hospital in 1926. We would recommend every medical student to study this address, for it is an impartial and frank setting out of the whole subject: there are pros and cons since the War; the practice of medicine does not often lead to wealth, but it does lead to a life of absorbing interest and of utility to one's fellow men. Chapter IX, "the meaning and methods of success," is almost an expansion of the previous chapter. It is wholly delightful to read, full of aphorisms and apposite quotations,—full, too, of commonsense. In this address we consider that Sir Humphry Rolleston has reached the happiest vein, and we regret that we cannot quote from it at length. A phrase, perhaps, may sum it up: the *patient* is as important as the disease from which he is suffering; and if you neglect the former in the interests of the latter, your practice is doomed. Even though a fellow human being is suffering from disease, he still remains (until he is dead) one of our human fellow sufferers; this should not be lost sight of. The rule is "put yourself in his place." Finally—and very important—is the lesson that the medical man must keep himself fit; he must take his regular exercise, enjoy social amenities, live a life which is not utterly bounded by his professional interests alone.

Chapter X discusses the problem of lady doctors. Lately their numbers at the medical schools in Great Britain has tended to decline, and Sir Humphry Rolleston frankly discusses the reasons for this. On the other hand—and in India in particular—the demand for them is almost insatiable. But there are certain drawbacks—chiefly casualties due to marriage. (We recall that a recent statistical investigation amongst the causes of casualties amongst the nurses at the Presidency General Hospital, Calcutta, led to a similar deduction: the trouble about the competent lady doctor or well qualified nurse is that some selfish male creature carries her off into the trammels of matrimony without considering how her patients, both present and future, may be concerned.) Thirty per cent. of lady doctors marry after qualifying, and are thus lost to the profession. It is all very well for the "stronger sex" to claim that she has equal rights; the cardinal trouble is that she surrenders them at the claim of the more insistent one. Our author claims that medical women are more intuitive than medical men, but perhaps less logical, less qualified to follow out a clue to its destination, "to search and study out the secrets of nature by way of experiment." They are more hard working students than the males, but perhaps they are less blessed with the sense of humour..... We do not know..... in brief, we do not presume to do so.

Chapter XI deals with irregular practice and quackery. It deals chiefly with the subject from its historical aspect, and this chapter should be read by every medical man; it is most intriguing, most humorous, most admirably put together. Perhaps the most illustrious of all quacks was George Berkeley, once Bishop of Cloyne, admittedly one of the most accomplished, learned, and wisest of men, who advocated as a universal panacea to avert and cure all evils a decoction of water with which tar in the proportion of a quart to a gallon had been mixed, and after two days the resulting supernatant fluid was drained off and swallowed *ad lib.* Quacks accredited to Royalty in earlier days present an interesting picture; we can only thank Heaven that H. M. the King-Emperor was treated during his recent and extremely critical illness by fully qualified medical men, amongst whom the author of this book, Sir Humphry Rolleston, was prominent; had His Majesty been treated by quacks, or even by medical men whose science was ten years out of date, we venture to believe that he would not have recovered. It was modern scientific medicine, and not some ancient system of pseudo-medicine, or some pseudo-modern "system" of "therapeutic" that accomplished the marvel,—for it was nothing less.

Chapter XII is devoted to "poetry and physic." Again, it is wholly delightful to read. Medicine has always attracted the poets; and the poets, medicine; though Shelley deserted the former for the latter. "Can a doctor be a poet?" asks our author. We do not know, but we doubt it; the doctor deals too much with reality to enter into the realms of imagery. Of course doctors have been poets—but usually either bad doctors, or bad poets. Keats in one of the most exquisite of England's song-birds, but he was no doctor; he took his L. S. A. in 1816, but never practised. Goldsmith may have had a medical qualification (the matter is doubtful), and even Conan Doyle deserted medicine as soon as he could, and "deserted the correction of astigmatism and errors of refraction for the detection of hypothetical crime." Sir William Osler was not a poet, but he stands out for ever as a man who combined the most perfect and polished English prose with the practice of medicine.

Chapter XIII of the book deals with the medical aspects of Samuel Johnson, and is a brief but adequate summary of the many illnesses from which that wonderful cynic suffered. Samuel Johnson suffered, amongst other complaints, from oedema of the legs and scrotum. On the morning before he died he performed venesection on himself, withdrawing some ten ounces of blood. This was apparently too much for him, for he was very debilitated, chiefly from the effects of asthma. The post-mortem was conducted by Dr. J. A. Wilson, who was Johnson's medical attendant in his fatal illness, and who had been requested by the latter to carry it out. Details are given in this chapter, quoted from the original records of 1784. Chronic interstitial nephritis would appear to have been the real cause of death, associated with high blood-pressure. "My diseases" once remarked Johnson, "are an asthma, a dropsy, and what is less curable, seventy-five." It is a terse summary which is applicable to many and many a case seen in present day medical practice, nearly a century and a half later.

* * * *

We have tried to convey to the reader—and, we fear, at some length—the historical, clinical, and professional interest of this book. It is one written by one of the most famous of present-day British physicians, a successor to the Regius Professorship of Medicine at Cambridge of Sir William Osler, and one on whom the latter's literary as well as professional mantle has descended. We can only hope that our readers will enjoy the reading of it as much as we did ourselves. It is a notable contribution to the philosophy of medicine.

R. K.

MEDICINE MONOGRAPHS. VOLUME XIV, EPILEPSY.—By William G. Lennox and Stanley Cobb, London: Baillière, Tindall & Cox, 1928. Pp. 197, with 3 tables and 14 figures in the text. Price, 16s. net.

VOLUME XIV of the well known series of *Medicine Monographs* is devoted to a consideration of the syndrome epilepsy; the preparation of the monograph has been entrusted to Drs. Lennox and Cobb, of the Harvard Medical School.

The first portion of the book comprising some 25 pages is devoted mainly to a consideration of the neurological mechanism of convulsions, with special reference to the different theories of causation. The conclusion is reached that none of the theories in question—the irritative, the release, the short circuit, or the explosive,—is by itself satisfactory, and that probably all seizures result from combination of two or more of these mechanisms. The rest of the book is taken up with a discussion of the factors involved in convulsions. In no other disease condition possibly have so many diverse aberrations in bodily function been arraigned as etiological factors; physico-chemical changes in the nerve cells, psychogenic causes, abnormalities in the circulatory, gastro-intestinal and sympathetic nervous systems, in the ductless glands or in the acid-base equilibrium of the body, all have had their day. The authors of this monograph present the claims for each and all of these various factors, together with the experimental data bearing thereon, in an admirably comprehensive and lucid style. A short summary at the end of each section is of considerable assistance in crystallizing the reader's ideas on what has immediately preceded, while the whole subject is excellently recapitulated in the last six pages of the book under the heading "general conclusions."

In the present state of knowledge (or lack of it) Dr. Lennox and Dr. Cobb have said what is essentially the last word on the subject of the syndrome epilepsy, and their manner of presenting the facts, separating the essential from the unessential, the data of value from the haphazard and casual observation, the wheat from the chaff, might well be imitated in other fields. Mention should also be made of the comprehensive bibliography containing over six hundred references together with authors' and subjects' indexes.

Of actual errors, the reviewer detected only two both of printing-room origin. On p. 34, line 2, "sensibility" should read "sensitivity" and on p. 63, line 9, "in often times" should be "is oftentimes." The general get-up of the book is good and in view of the excellence of its contents the price is not excessive.

J. M. H.

A HANDBOOK ON DIABETES MELLITUS AND ITS MODERN TREATMENT.—By J. P. Bose, M.B. (Cal.), F.C.S. (Lond.). Calcutta: Thacker, Spink & Co., 1928. Pp. 192, with 1 colour plate and 7 charts. Price, Rs. 5.

We believe that this little handbook will prove invaluable to medical practitioners in India, and especially to those in Bengal, in which Province diabetes is so prevalent. It has a foreword by Col. J. W. D. Megaw, I.M.S., and is dedicated to the memory of the late Rai Bahadur Dr. A. Mitra of Kashmir, whose widow endowed the Mitra Research Scholarship in diabetes at the Calcutta School of Tropical Medicine, which the author has held during the past seven years. Further, the volume is well published, well bound, and has been published at a price well within the reach of the pocket of the medical practitioner and student in India.

The book consists of 15 chapters and 3 appendices dealing with the whole subject of diabetes as met with in Indian practice. The first chapter deals with the progressive knowledge with regard to diabetes, and includes a very clear and lucid account of the discovery of insulin and subsequent developments. In Chapter II the author defines diabetes as a constitutional disorder due to deficiency in the secretion of the islets of Langerhans in the pancreas,—thus at once excluding such complications as renal glycosuria. Here he fully discusses the

predisposing causes of diabetes, with special reference to India. Alimentary glycosuria he regards in general as a pre-diabetic state. Blood-sugar curves, given throughout the book for different types of individuals, give it a special value. In India, sums up the author, the causation of diabetes may be traced to "a combination of ill-balanced diet, over-eating, disinclination to any form of active physical exercise, excessive intellectual work, sedentary habits, and too much worry inseparable from the present struggle for existence. The Bengalee Hindus appear to be more prone to get diabetes than the other races living in India." A curious finding by the author is that students for the Diploma of Tropical Medicine at the Calcutta School of Tropical Medicine showed a special tendency to develop glycosuria after their examination, thus illustrating the well-known fact that nervousness and worry may bring on temporary glycosuria.

In Chapter III the general carbohydrate metabolism is fully explained, and here the value of the glucose-tolerance test is brought out in a series of diagrams of great value. Chapter IV considers the inter-relationship of the endocrine glands in sugar metabolism and gives a summary of research work carried out by the author in conjunction with Colonel Acton. The influence of colour in the reaction of rabbits to adrenalin and insulin tests is emphasised. Chapter V deals with the morbid anatomy of diabetes; there are few diseases which leave less obvious changes in the internal viscera. Chapter VI, which is devoted to symptomatology, is brief, but sound. The first symptom to draw attention to a diabetic condition may be ocular, or a persistent pruritus, a carbuncle, or a severe neuralgic pain. Chapter VI deals with diagnosis, and here glycosuria, and especially renal glycosuria, are sharply differentiated from true diabetes mellitus. The time of day when the urine is examined is of great importance, for even true diabetics may give no sugar reaction if fasting. In Chapter VII diets for diabetics are considered, with a general summary of the best well-known diets to-day in vogue; a most useful appendix gives suitable diets for Europeans, Indian patients on a mixed diet, and vegetarian Indians who are suffering from diabetes.

Chapter IX deals with insulin therapy. Here there is presented in brief summary the whole of present-day insulin therapy, its use, its dangers in the tropics, its value, and its limitations. This chapter is admirable in its detailed account of the subject, written especially from the view of medical practice in the tropics. Chapter X considers the complications of diabetes and the diabetic patient in surgery; chapter XI, illustrative cases; chapter XII, glycosuria and life insurance, where most useful advice is given; the patient should be given a drink of glucose when first appearing before the examiner, and his urine tested 1 to 1½ hours afterwards. Chapter XIII deals with observations on the blood chemistry of Indians in normal health and in disease, and summarises a large volume of experimental observations. Chapter XIV details a simplified method for estimation of blood-sugar, suitable for the general practitioner in the tropics, and described by the author in our issue for February 1928. This is eminently practicable, and should obviate the dangerous practice of treating cases of diabetes by observations on the urine alone, unaccompanied by tests for the blood-sugar. Finally, the three appendices deal respectively with the calorific value of different Indian foodstuffs in common use; a classified list of Indian green vegetables according to carbohydrate content; and an account of the life of the late Rai Bahadur Dr. A. Mitra.

We would classify Dr. Bose's book as being eminently practical and essential to the general practitioner. The amount of important clinical information included within its few pages is amazing. It is the outcome of seven years of intensive study devoted to the problem of diabetes as it occurs in Bengal. It is a *vade-mecum* which will prove of great value to the general practitioner in the tropics, whether in Bengal or elsewhere. Finally, we would like to welcome the book as a new addition to the ever growing list of specialist publications

issued from the Calcutta School of Tropical Medicine by authors who have devoted several years of work to the specialised study of the subjects concerned. Such professors naturally commence by relying on the published works by other authorities; sooner or later, however, they realise that their own problems are such that nothing less than to deal with them in book form for the benefit of their brother medical practitioners who are faced with the same problems, is adequate.

Dr. Bose's contribution to the subject is in every way satisfactory; it is complete, concise, informative well published, and well illustrated. Finally, its price is very moderate.

FASCIAL GRAFTING IN PRINCIPLE AND PRACTICE.

—By H. C. Osslin, O.B.E., F.R.C.S. (Edin.).
Edinburgh and London: Oliver and Boyd, 1928.
Pp. 92, with 21 plates. Price, 7s. 6d. net.

THE use of the fascia lata in the repair of defects of the soft parts and even of the bones has assumed increasing importance of late years, as the ability of portions of this tissue to survive as free grafts even under apparently unfavourable circumstances has been more widely utilised. In this little work we have an account of the technique of the principal operations in which the fascia lata is utilised, prefaced by some useful introductory matter on its anatomy and histology, which show that it is not a matter of indifference from which portion the graft is taken. The author appears to have interested himself principally in the use of the fascia to prevent recontraction after dissecting out adherent scars and he is to be congratulated on some of the results here illustrated. There is a good account of Gallie and Lemesusice's work and its applications, and Hey Grove's methods are freely quoted in the descriptions of the arthroplasties. The book should be useful to surgeons.

W. I. H.

SYPHILIS—A TREATISE ON ETIOLOGY, PATHOLOGY, SYMPTOMATOLOGY, DIAGNOSIS, PROGNOSIS, PROPHYLAXIS AND TREATMENT.—By Henry H. Hazen, A.M., M.D. Second Edition. St. Louis: C. V. Mosby Co., 1928. Pp. 643, with 165 illustrations including 16 coloured figures. Price, \$10.

THE first edition of Dr. Hazen's well-known work on syphilis appeared in 1919, and we congratulate the author that the second edition is no larger despite the fact that many sections have been rewritten. All aspects of the disease are fully considered, and it is impossible in a brief review to do more than refer to a few salient points. After the introductory chapters a section on pathology follows written by Major Matthew Reasoner. Next the clinical aspects are fully described. These are followed by chapters detailing the lesions of special tissues. These include syphilis of the nails and hair, of the mouth and throat, of the respiratory tract, of the digestive tract, of the vascular system, of the bones and joints, of the endocrine glands, and lastly of the central nervous system. The sections on syphilis of the genito-urinary organs, of the eye and of the ear, are contributed by specialists on those subjects. This is followed by a very adequate chapter on congenital syphilis. The chapter on serological tests is from the pen of the well-known authority Dr. Charles F. Craig. The final three chapters are devoted to prognosis, prophylaxis and treatment respectively. Under the head of treatment the author states that in his experience the percentage of permanent cures is much higher in those cases in which the Wassermann reaction is positive before treatment, and he adds "it would seem possible that the extremely early treatment of syphilis may on occasion prevent the development of a natural immunity." While this opinion is directly opposed to the experience of others, the suggestion is an extremely interesting one and the last word on this subject has by no means been heard. The description of the malarial treatment of syphilis of the central nervous

system is very inadequate, and the reader is left with the impression that the author is undecided as to its value. Under prevention, the difficult question of sexual instruction of the young is touched upon, and the author is in agreement with the view now very widely held that the facts of life should be taught to children through the medium of a course in general biology, commencing with the development of flowers and terminating with that of mammals, rather than by *ad hoc* sexual instruction which is probably undesirable. The coloured plates, the most interesting of which are those showing the cystoscopic appearances of secondary and tertiary lesions of the bladder, are extremely good. The book is beautifully got up and printed on good paper. The illustrations which depict every phase of the disease are of excellent quality. Numerous radiographs are included. The book may be strongly recommended to students and practitioners. Our only criticism is its excessive weight, due presumably to a heavy type of paper being necessitated by such a wealth of illustration.

R. B. I.

THE DUODENUM, MEDICAL, RADIOLOGIC AND SURGICAL STUDIES.—By P. Duval, J. C. Roux and H. Beclere. Translated by E. P. Quain, M.D. St. Louis: The C. V. Mosby Company, 1928. Pp. 212, with 127 illustrations.

EVERY clinician must have come across cases of "dyspepsia" presenting symptoms so indefinite that the most experienced observer is at a loss to decide definitely in which of several closely related organs the cause lies. Cholelithiasis, duodenal ulcers, appendicitis, etc., are usually clearly recognisable, but the class of cases here considered present borderline symptoms and fail to react satisfactorily to medical treatment, nor is surgical intervention likely to be successful unless the operator possesses the experience necessary to interpret the significance of all the abnormal findings in all the doubtful viscera.

It is in this class of case that team-work is so essential, and here we have a monograph by a physician, a surgeon and a radiologist, assisted by a chemist. It does not deal with duodenal ulcer, but with duodenal obstruction caused by inflammatory or congenital conditions, which may be just as disabling as ulcer and nearly as dangerous to life. The subject falls into three divisions, (a) periduodenitis due to cholecystitis, (b) bands and adhesions of doubtful origin uniting the duodenum to the biliary apparatus or obstructing the third and fourth portions, and (c) obstruction of the duodenum by the superior mesenteric artery. An analysis of the pathogenesis and symptomatology of each of these groups is accompanied by a series of radiologic studies and by numerous illustrative case histories. The treatment is always surgical and in the authors' opinion duodeno-jejunostomy is the operation of choice in cases with low obstruction and gastro-enterostomy, combined with separation of adhesions and omental grafting, when the stenosis is higher up. There is a good account of the technique of duodeno-jejunostomy and a discussion of the causation of the severe symptoms of intoxication which appear so rapidly in obstructive lesions of the duodenum. The book is one which we recommend to the perusal of every internist, surgeon and radiologist as giving a lead in the solution of the obscure problems presented by many cases.

W. L. H.

DIAGNOSIS OF CHILDREN'S DISEASES.—By Dr. E. Feer. Translated by Carl Ahrendt Scherer, M.D., F.A.C.P. Second Edition, Revised. London: J. B. Lippincott Company. Pp. xxvi plus 551. Price, 35s. net. Available from Messrs. Butterworth and Co. (India), Ltd. Price, Rs. 26-4.

THE appearance of the second English edition of *The Diagnosis of Children's Diseases* by Professor E. Feer, translated by Dr. C. A. Scherer, after three years shows that it is much sought after. Like its predecessor, it deals with diagnosis only: treatment

and pathology are outside its scope. It may seem surprising that over 530 pages should be devoted to this subject exclusively: although some reduplication is inevitable, it is reduced to a minimum. There are 266 excellent illustrations and three beautiful coloured plates. It will form a very useful addition to the library of everyone interested in pediatrics. When eventually the study of diseases of children (which is most essential to every general practitioner) is made compulsory by the General Medical Council instead of one of the useless courses, such as x-rays, which is at present compulsory, this volume will be most welcome to every student, if only for its illustrations.

The points to criticise are few. There is no mention of the common occurrence of squint and nystagmus in monologism. Infantile scurvy is said to be "extremely uncommon," and the "black eye" due to it is not mentioned. The use of lipiodol in the diagnosis of bronchiectasis is not referred to: and we think that the use of two vague terms like "croup" and "pseudocroup" without defining what is meant, is very much to be deprecated. We do not agree that the abdomen in intussusception after a short time becomes painful on pressure, or that visible peristalsis is an "important diagnostic sign." The common occurrence of a palpable tumour in congenital stenosis of the pylorus is not described.

The acute and chronic nutritional disturbances of infants are fully dealt with: the classification of Finkelstein as well as that of Czerny and Keller is well described. The book is fully indexed: it is beautifully printed and well bound. The publishers, Messrs. J. P. Lippincott & Co., are to be congratulated: Messrs. Butterworth & Co., Calcutta, are the agents in India.

S. A. M'S.

NUTRITION.—By Walter H. Eddy, Ph.D. London: Baillière, Tindall and Cox, 1928. Pp. vii plus 237, with 37 tables. Price, 11s. 6d. net.

IN the first part of this book the author has attempted the very difficult task of writing a general account of the science of nutrition for non-scientific readers. To do this logically would require either a considerable preliminary treatise on elementary chemistry and physics, or a presumption of some small and definite amount of knowledge of these subjects. The author has not consistently followed either of these alternative plans. In places, (e.g., in the description of the essential similarity of burning fuel in a furnace and food in the body) no previous knowledge has been presumed. In many other places (e.g., on the respiratory quotient) a fairly considerable knowledge of chemistry is necessary to follow the argument. The result is that to a strictly non-scientific reader the book will be unintelligible, while to one already acquainted with the elements of nutrition this part of the book will be superfluous.

The second part of the book deals at length with the vitamins, and the methods of testing the vitamin content of food-stuffs, etc. Here the author is on the part of the subject to which he has obviously given special attention, and consequently here he puts the matter clearly and intelligibly. *Ce que l'on conçoit bien s'annonce clairement.* It is an account which can be read with interest both by intelligent laymen and by scientists who have not made the vitamins their special study.

C. N.

REQUISITES AND METHODS IN SURGERY.—By Charles W. N. Cathcart, C.B.E., M.A., M.B., C.M. (Edin.), F.R.C.S. (Eng. & Edin.) and J. N. Jackson Hartley, O.B.E., M.B. (Edin.), F.R.C.S. (Eng. & Edin.). Edinburgh: Oliver and Boyd, 1928. Pp. 476, with 246 illustrations. Price, 12s. 6d. net.

THIS is an excellent little book on minor surgery. The method of dealing with the subject is new, clear and lucid. The chapters on "Medico-Legal Notes,"

"Post-Mortem Examination" and "Hospital Economy" are valuable additions to a hand-book on minor surgery such as this. The book is illustrated by copious helpful diagrams. It will be found a most useful book, not only by students of medicine but also by doctors in general practice.

P. B.

CLINICAL SURGERY.—By J. W. Dowden, M.B., F.R.C.S.E. Edinburgh: Oliver and Boyd, 1928. Pp. 68. Price, 2s. net.

THIS little pamphlet is meant as an introduction to clinical surgery for junior students and is quite original in its scope. It is an effort to teach students how to examine and treat a case. The author rightly emphasises the importance, which is most often forgotten by students, of utilizing their senses in the examination of cases in an orderly and rational way. Not only is emphasis laid on this point but also on the value of facts as opposed to theories. It is meant to teach students to be systematic in their methods of study and how to use to best advantage their personal gifts and powers of observation in the diagnosis and treatment of surgical cases. This book will be found invaluable by students of medicine.

P. B.

OPERATIVE SURGERY.—By J. Shelton Horsley, M.D., F.A.C.S., Attending Surgeon, St. Elizabeth's Hospital, Richmond, Va. Third Edition. St. Louis: The C. V. Mosby Company, 1928. Royal 8vo. Pp. 893, with 756 illustrations. Price, \$15.00.

TEXTBOOKS of operative surgery may usually be placed in one of two classes. The first consists of a description of the standard operations of surgery, including many obsolete operations and omitting many of the most recent. The second records the author's own practice, and his comments on the present-day procedure of other surgeons. It is essentially to the second class that this volume belongs and its appeal therefore is to the surgeon rather than to the examination candidate.

The opening chapter is an abstract of the author's paper on "The Value of Biologic Principles in Surgical Practice" and contains much thoughtful criticism of operations which had and still have a vogue.

The chapter on surgical drainage sets out the principles which should be the guide for every surgeon, but which are too frequently ignored.

When we come to the chapter on surgical technic, the description is somewhat sketchy and it should rarely be necessary to control hæmorrhage in an abdominal incision by whipping over the muscle as depicted in Fig. 26.

A chapter is devoted to transfusion of blood and all the standard methods are described. The author has also done a large amount of experimental work on the suturing and anastomosis of blood-vessels and gives us the benefit of this work in an interesting chapter: periaxillary sympathectomy is briefly described, though obviously the author is not enthusiastic over the results. We are surprised to note that incipient gangrene is not included as an indication for the operation. It is these cases that certainly furnish the most striking results the reviewer has seen. The author advocates ligation of the femoral vein in cases of impending gangrene of the leg, but we see no reason why this should not be combined with periaxillary sympathectomy. The ligation of the main arteries is carefully described, but a notable omission in the reviewer's opinion is the description of Quervain's technique for the inferior thyroid.

In dealing with aneurisms requiring ligation of the common carotid, various methods are suggested for avoiding cerebral symptoms, such as the temporary application of a Crile's clamp or partial occlusion by a metal band. The methods of dealing with arterio-venous aneurisms are described, though we are glad to see that the difficulties are not minimised even by

an author who has a wide experience of experimental work on arterial suture.

Plastic surgery is very fully dealt with and includes operations which are not usually found in British textbooks such as those for face lifting, removal of wrinkles, double chin, etc. The omission of any reference to the Addison relaxation incision in operations for cleft palate should be rectified.

The remainder of the volume is made up of chapters on regional surgery, and all are very complete and include a number of operations that may still be regarded as on trial, as well as those more generally recognised. Although several operations are described for hernia, Gallic's operation has not been included, an omission which will surely be rectified in subsequent editions.

In gastric surgery a great deal of space and discussion is devoted to the author's operation for pyloroplasty. This is an operation which is performed much more frequently than present-day surgical literature would lead one to suspect. Some of our most advanced surgeons are firm advocates of it and it is encouraging to find it has equally firm advocates on the other side of the Atlantic. When gastrectomy is called for the author uses his own modification of Billroth I, wherever possible. The modification he advocates would seem to simplify the operation and make it safer. The chapter on stomach operations is very complete and includes a note on the physiology of the stomach which surgeons are apt to overlook in their enthusiasm for new procedures. Notable omissions in the chapter on abdominal incisions are the Battle incision, though it is admittedly falling into disuse, and the Kocher incision for gall-bladder operations.

The volume concludes with chapters on genito-urinary operations, all of which are fully discussed with their accidents and complications such as division of the ureter. Gynecological operations are omitted.

The book is well printed and the illustrations numerous and excellent. It is written in a style that is eminently readable and nearly every page has some point of interest that repays perusal. The author describes the operations in a free running style quite distinct from the usual textbook division of an operation into so many steps. It is not only a book to which a surgeon may turn for details of an operation, but one which he can pick up and read with pleasure and profit in his moments of leisure, if he has any.

A. H. P.

MATERNITY AND CHILD-WELFARE.—By A. P. Pillay, O.B.E., M.B., B.S. and M. Subramanyam, M.B., B.S., B.Hy., D.P.H., D.T.M. & H. Sholapur: The Maternity and Infant Welfare Association, 1928. Pp. vii plus 94, with Appendices and Index. Price, Rs. 3.

"THE first axiom of infant-welfare work is often misunderstood, that its object is not so much to save infant life as to secure health to infants that survive."

These very significant words of Dr. Balfour quoted on page 10 of Dr. Pillay's maternity and child-welfare deserve the very closest attention of every reader of this useful little book; for the greatest obstacle to the maternal and child-welfare movement in India is not so much the ignorance of the illiterate masses as lack of interest and apathy on the part of the educated classes, both Indian and European. Too often people take the view that successful child-welfare work can only intensify the evils of over-population; and because of this mistaken notion they either deliberately oppose it or give it only lukewarm support.

This book is not intended merely for doctors and nurses; but all who can understand English should read it, so as to get a clear understanding of what is meant by maternal and child-welfare work and what can be done in this direction both in towns and rural areas in India, even with very limited resources. This is all the more necessary because, as Dr. Pillay points

out in his preface, "Even our medical men and women and social workers are surprisingly ignorant of what maternity and child-welfare work is."

Dr. M. I. Balfour contributes the opening chapter on the history of maternity and child-welfare work in India and traces the beginnings of the movement back to the sixties of the last century. But apart from the work of this nature organised in Bombay by Lady Willingdon and Lady Lloyd little of permanent value was accomplished, until in quite recent times the All-India League for Maternity and Child-Welfare was established by Lady Chelmsford and the All-India Baby Week was inaugurated by Lady Reading.

Chapter II explains the need for maternity and child-welfare work in India and naturally lays very great stress upon the very high rates of mortality. Nevertheless attention is called to the fact that "A high infant mortality not only implies the loss of many infants but also:—

(a) the maiming of many surviving children, for conditions which kill some, only injure others;

(b) a high death-rate in the next four years of child life; and

(c) the existence of unhealthy conditions in the mothers and in the home life of the people."

Chapter III is devoted to a description of welfare organisations and explains "how to make a start with work of this kind."

Chapter IV describes simple forms of welfare work and is especially useful and stimulating, as the following paragraph will show:—

"The simplest and cheapest form of work and one that could be adopted even in the larger villages is for a few ladies to form themselves into a committee, get on loan or hire a room in some convenient locality and hold, once or twice a week, informal talks to the women in the neighbourhood, teach them the preparation of baby feeds, sewing, and occasionally get doctors and others to give lectures and if possible magic lantern demonstrations on the care of the mother and the baby."

"The ladies may not know much at the beginning but they are sure to pick up in time."

Chapter V discusses the health visitor and points out that she is always the central figure in maternity and child-welfare campaigns. Courses of training for health visitors are also described, but it is not quite clear why the author should speak of a vernacular course "as a necessary evil." Chapter VI deals with the question of help required by women during confinement, in the form both of maternity homes, etc., and the training of midwives and *dais*.

In Chapter VII and VIII Miss R. Piggott and Dr. DaGama give their experiences in the training of *dais*. Over 350 *dais* have been trained in Sind and over 200 in the Poona district.

Chapter IX is devoted to ante-natal clinics and welfare centres. Any town or village which has a visiting midwife or health visitor can start a "centre" says Dr. Pillay. "A small room will be sufficient in the beginning." Apart from the special welfare work of the centre, including the keeping of records and the weighing of children, various other side activities are suggested, such for example as classes on mother craft, infant and invalid cooking, cutting out and sewing clothes, domestic hygiene and home nursing health and welfare talks and lectures by doctors and other qualified persons; magic lantern and cinema demonstrations and feeding of children and expectant mothers. The author takes care to point out, however, that if any of these activities are undertaken special accommodation or a large hall will be necessary.

In Chapters X and XI Dr. Tilak deals with propaganda work and points out the value of the fullest possible co-operation between all official and non-official agencies. "Nearly a million and a half men and women in about 4,000 places," says Dr. Tilak, attended the lectures or shows organised by the Madras Health Council in co-operation with the Department

of Public Health during 1926, largely owing to the great interest taken in this form of propaganda by the Collectors of the Madras Presidency.

Chapter XII describes day nurseries and homes for children. "In India the poverty and bad housing conditions make the opening of crèches in the poorer localities of towns a great necessity." There would seem to be a special need for such institutions in industrial areas, etc., and managers of mills, tea gardens, etc., employing female labour may find useful hints regarding the organisation of day nurseries in this chapter.

Chapter XIII refers to welfare work among children of pre-school age, including nursery schools, etc.

In Chapter XIV welfare work in rural areas is taken up and the suggestion is made that "the question of improving confinement rooms can be most easily tackled and the opening of small though rudimentary maternity homes is also not beyond practical politics."

The next chapter deals with record keeping and then come two more on how Government and local authorities can help formal maternal and child-welfare. Several final chapters are then devoted to a description of work in England, together with a summary of the legislative enactments in force in Great Britain in regard to child and maternal welfare.

A further valuable feature of the book is a series of 12 appendices in which are given detailed suggestions regarding practical maternal and child-welfare work. The book may be strongly recommended as a most useful manual for everyone whether medical or lay, European or Indian, who can be induced to take a practical interest in maternal and child-welfare.

C. A. B.

PHYSIOLOGY AND BIOCHEMISTRY OF BACTERIA.
VOL. I.—By R. E. Buchanan, Ph.D. and E. I. Fulmer, Ph.D. London: Baillière, Tindall & Cox, 1928. Pp. xi plus 516, figures in the text 78. Price, 34s. net.

We hope that this is the commencement of a valuable series of books on the *Physiology and Biochemistry of Bacteria*. The work, although a compilation, gives the essential points that are required by advanced students in the study of these primitive forms of plants. The book makes one realise the great necessity of having a good knowledge of mathematics, physics and chemistry before undertaking a study of the physiology and biochemistry of the bacteria. The ordinary reader will not find much benefit from the book unless he possesses this knowledge.

We can, however, recommend the book thoroughly for advanced workers in research laboratories, as it contains a good deal of information that would otherwise have to be searched for in the literature: for example, the whole subject of agglutination, although dealt with briefly and systematically, gives a good general survey of the work on the subject, which is necessary before undertaking any research on it.

We congratulate the authors on the production of this most valuable work, and look forward to the additional volumes that are to complete the series.

H. W. A.

A TEXTBOOK OF PATHOLOGY.—By W. G. MacCallum. Fourth Edition. Thoroughly revised. London and Philadelphia: W. B. Saunders Company, Ltd., 1928. Pp. 1177, fully illustrated. Price, 45s. net.

DR. MACCALLUM'S *Textbook of Pathology*, first produced in 1916, has now reached its fourth edition. Various alterations in structure and arrangement have been made, but these it is not our purpose to record—at least in detail. What impressed us most in a survey of this new edition of the book is the change which appears to have taken place in the author himself. In none of his writings does Dr. MacCallum ever

show any evidence of bigotry or didacticism, but he now seems to have reached a plane of what one might almost call gentle pessimism. As an example, take the opening sentence of the last paragraph of that section of the book devoted to nephritis. "We are left as we began, with only momentary ideas as to the cause of nephritis....." this, be it noted, following on an exposition of the subject which can only be described as "masterly"—a much abused word, strictly applicable in this instance.

In the revision of a book of this size, it is almost inevitable that some portions should have been less carefully overhauled than others. The section on yellow fever, for example, is brief but fully up to date, including even the recent work of the late Adrian Stokes: the bibliography on the pathology of leprosy, however, contains no references later than 1914. The important work of Schobl on monkeys might usefully have been included in the yaws section: the pathology of kala-azar is dismissed in a few lines and the statement is definitely made that "the disease..... is transmitted by the bite of a fly, *Phlebotomus argentipes*." Chapter 52, p. 935, begins thus "The recent discussion of chronic affections of the joints at the International Congress of Medicine in London....." but on referring to the end of the chapter we find that the congress in question was held in 1913.

We hope that Dr. MacCallum will excuse this somewhat carping criticism: we feel that it is perhaps a little unfair in that the author does not make any pretence to cover the vast field of tropical pathology. To sum up, MacCallum's *Textbook of Pathology* has still further enhanced its reputation as a comprehensive and scholarly exposition of the science of pathology: in this field it has few compeers in the English language.

For their part in the production of this handsome volume the publishers fully merit the thanks expressed by the author in his preface.

J. M. H.

EXERCITATIO ANATOMICA DE MOTU CORDIS ET SANGUINIS IN ANIMALIBUS (AN ANATOMICAL STUDY OF THE MOVEMENT OF HEART AND BLOOD IN ANIMALS).—By W. Harvey, M.D. With an English Translation and Annotations by C. D. Leake. London: Baillière, Tindall and Cox, 1928. Pp. xii plus 228, with 5 plates. Price, 16s. net.

It was not to be expected that the tercentenary year of the publication of Harvey's "De Motu Cordis" would be allowed to pass without the appearance of new editions of this famous work. Furthermore, it is not surprising that at least one of these editions should be issued by a firm famous for their medical publications. Messrs. Baillière, Tindall and Cox have gone one better than publishing a new edition; they have published a new translation.

The volume is very complete; it contains a facsimile, not of the title or one or two sample pages only, but of the whole of the original 1628 edition. This is followed by the new translation, a translator's note, a chronology of the life of William Harvey and an index. There are also a number of plates. Amongst these are included reproductions of the most famous portraits of Harvey and of the original plate "Experiments on a bandaged arm."

In these days few members of the medical profession are able to read Latin with ease, but the majority of us can struggle through a Latin passage when we are interested enough to desire to know its full meaning. For this reason, in conjunction with the fact that the translation is a very free one, the reproduction of the Latin text is particularly welcome. There is, however, something very unsatisfactory about a facsimile reproduced by modern methods; the letters are never very clear cut and one finds oneself absent-mindedly cleaning one's glasses at very frequent intervals. The reproduction in this case is quite up to the average.

This is the third English translation to appear; there was a contemporary translation (1653), and in 1847 the Sydenham Society published Dr. Willis's translation. Dr. Chauncey D. Leake, though a professor of pharmacology in an American University, has produced a translation in very excellent English, with only a few of the less offensive American spellings, such as "fetus." There was plenty of excuse for a new translation; Dr. Willis's translation appears to have pleased few people, whilst the earlier translation appears to have displeased Dr. Willis. The reviewer is more fortunate than was Dr. Leake in that he possesses a reprint of the 1653 translation. The subsequent reading of the present translation gave him exactly the same type of shock as he imagines that he would receive when first seeing a Shakespeare play in modern dress. There is something improper in the appearance in modern English of some of Harvey's apparent naiveties, his putting forward as new ideas facts which not only every first year medical student but every elementary school child now knows. But when these are decently clothed in the English of Harvey's time all the impropriety is lost.

During the making of this translation there must have been many moments when the translator felt very uncertain of the line he should take; on at least one occasion, in our opinion, he made a wrong decision. "Vena arteriosa" and "arteria venosa" have been translated, almost throughout, as "pulmonary artery" and "pulmonary vein," respectively. One can see the translator's difficulty. "Arterial vein" of the 1653 translation did not please him, rightly; on the other hand, being a translator, one supposes that he felt he must translate. All went fairly well until the last chapter was reached. Then he found that if he continued to translate "vena arteriosa" as "pulmonary artery," this chapter would read as sheer nonsense: (in this chapter Harvey points out that the *vena arteriosa* is really an artery and the *arteria venosa* really a vein). He therefore adopted the procedure—which, in our opinion, he should have adopted throughout—of giving the original Latin in italics. The translator's irritation is reflected in his last footnote; he turns on the unfortunate Harvey and says "Since he so clearly points out the inconsistencies of the current names, why did not Harvey rename the vessels? One may sometimes be too deferential to traditional authority." Surely this criticism is grossly unfair. Dr. Leake, a pharmacologist, is perhaps not as troubled by kaleidoscopic nomenclature as are his protozoological and entomological colleagues or, we feel, he would not have suggested this. In his day Harvey was doubtless considered a hot-headed young revolutionary by many of his colleagues, but had he tried altering traditional names he would certainly have been considered a lunatic and treated as such. He put forward arguments as to why the names at that time in use were unsuitable. When his opinions were universally accepted then would be the time to effect the alteration.

The printing, paper and binding are excellent. A copy of this book should form part of the library of every medical institution and of every doctor who takes any interest at all in the history of the science he has adopted.

L. E. N.

MODERN MEDICINE.—Edited by Sir William Osler, Bart., M.D., F.R.S. Third edition, thoroughly revised and re-edited by Thomas McCrae, M.D. Assisted by Elmer H. Funk, M.D. General Index. London: Henry Kimpton, 1928. Pp. 126. Sold in sets only. Six volumes and index £12 12s. net.

WITH the publication of this volume, Osler's world-famous system of medicine is complete. This, the third edition, was planned during Sir William Osler's lifetime, but he died more than a year before the first volume appeared; the work of editing this edition of "Modern Medicine" has been very ably carried out by Dr. Thomas McCrae. The six volumes and the index have appeared within a period of about three years and

there was an interval of twelve years between the second and third editions, so that the prospective purchaser need have no fear that his edition will become a back number shortly after he has bought it.

As an index the volume under review is all that an index should be, the type is clear and well spaced, the paper is of good quality and easy to turn, and the binding is strong and in keeping with the other six volumes of the edition.

L. E. N.

CHOLERA AND ITS TREATMENT.—By Ramkrishna Guln, L.M.F., Bengal Medical Service. Calcutta: The Book Co., Ltd. 1929. Pp. 76, with 5 Illustrations. Price, .

THIS is a useful and practical little manual. The author was house physician and resident medical officer, infectious diseases wards, Campbell Hospital, Calcutta, and served under that veteran teacher Rai Dr. Lal Behari Ganguli Bahadur, who has been in charge of the cholera wards at the Campbell Hospital for very many years, whose practical experience in the treatment of the disease is probably unrivalled, and to whom the book is dedicated. As a result the book is essentially a practical one, written from personal experience and therefore of value.

The bacteriology of the cholera vibrio is very scantily dealt with, but the sections devoted to diagnosis, differential diagnosis, and above all, treatment, are very sound and well written. The author regards the essential oils' mixture as of prophylactic rather than therapeutic value, and adheres to hypertonic and other saline infusions as the sheet-anchor of treatment for severe cases. He is of opinion that repeated small fractional doses of calomel have a definite value in the treatment of cases seen at an early stage, and his notes on the indications for atropine are interesting. Formule for stimulant and alkaline mixtures are also given.

This little book should prove useful to medical practitioners throughout India. It is well printed, well bound, and well illustrated. It is marred, however, by numerous printer's errors, which we should like to see corrected in a second edition.

R. K.

MEDICAL AND ALLIED TOPICS IN LATIN POETRY.—By Heinrich Oppenheimer, D.Lit., LL.D., Ph.D., M.D., M.R.C.P., Barrister-at-Law. London: John Bale, Sons & Danielsson, Ltd. 1928. Pp. vii plus 445. Price, 30s. net.

ONE's sympathy goes out at once to the author of this delightful volume, who states in the preface that during the War he was regarded as an enemy alien, and, having been subjected to social ostracism, sought comfort in the company of the classical writers. Further, one learns from his preface that having been struck down with a serious illness, he believes that this work is of the nature of a valedictory gift to his medical confrères. Truly we hope that this will not be the case, for the book was very well worthy of publication; it is erudite, delightful, pleasing; it may have but few readers, but those who browse in its pages will enjoy it to the full.

Luckily for its readers, the author has appended throughout English translations to the Latin passages quoted. However much we may have enjoyed (or not) ploughing through the *Æneid* in our schoolboy days, there are unhappily but few of us who in our maturer years can translate a Latin passage at sight. And the translations are extremely well chosen; some are the author's own; the majority however are from well known and universally accepted English metric translations. Dryden, Rowe, King, Dove's *English Classics*, Cranstoun, and other well-known translators have all been resorted to. (And in this connection the reviewer may recall a most apposite remark made by one of the most distinguished men in the field of scientific research of to-day to the effect that one of the world's greatest losses was the abandoning of Latin as the universal language of Science and Medicine. This we believe to be true. Had we adhered to Latin as the second language for

every scientific student, and were all scientific and research papers to-day published in Latin, we should at once have had a universal scientific language in which all journals and textbooks would be published, and every discovery published would immediately be accessible to all workers on the subject. There would be no need for translations, and the freest intercourse on scientific matters would be possible between all nations.)

The book covers a very wide field: physicians, divine and heroic; medical sociology; physiology; surgery; diseases of the eye; of the nose, throat and ear; infectious diseases; internal disorders; materia medica; dietetics; balneology—in which the ancients excelled; toxicology; alcoholism; neurology; sexology—if we may be permitted to quote that malphonious term; midwifery; dermatology; cosmetics; nursing; and medical metaphors are among the many and most diverse subjects to which chapters are devoted. A good index completes the volume.

One cannot "review" this book; one can only "browse" through its pages—a course which the author himself recommends. The author hopes that "here and there some congenial soul may derive as much pleasure from devoting an hour of leisure after a hard day's work to turning over its pages as the writer has found in compiling it." This hope is fully justified; there is a wealth of literary and educational material in its pages. For example, who would forego the true and inner history of Aesculapius' serpent, or the chapter on medical sociology, the relations of doctor and patient in the ancient days, the medical education in the Roman Empire that was? The snake it was, according to ancient beliefs, whose breath resuscitated the dead to life—or possibly the healing herb which it brought in its mouth.

Under the later Empire physicians apparently came to be of little repute, and Juvenal in his *Satires* comments on their failings with a caustic pen. Even Ovid sometimes descends to the sarcastic vein:—

"He that by the physician has been left
Yet of all hope is not bereft."

One of the most interesting features of the book is its frequent reference to quartan ague as a rather fatal disease. Quartan malaria to-day is rather apt to be a mild but persistent infection; one wonders whether the virulence of this disease has changed within the last two thousand years.

We have no space in which to comment further upon this most charming volume, though we wonder whether Cleopatra really suffered from syphilis, as suggested on p. 343.

Emphatically a book for leisure hours, and a book for the *littérateur*. But

"When we know not how our ills arise,

Nor whence they come, our way in darkness lies," a quotation which may be applied to much of even modern present-day scientific medicine.

We hope that Dr. Oppenheimer's estimate of the success of his own book may be a mistaken one; there is here many an apposite quotation, and many a page and chapter full of information—ancient, perhaps, but very applicable to modern times.

R. K.

A PATIENT'S MANUAL OF DIABETES.—By H. W. Moxon, B.A., M.R.C.S. (Eng.), L.R.C.P. (Lond.). London: H. K. Lewis and Co., Ltd. 1929. Pp. xii plus 132. Price, 6s. net.

THE keynote of success in the treatment of diabetes depends to a large extent on the intelligent co-operation of the patient, and for this an intelligent understanding of the nature of the malady is a great help to him. It is encouraging to find that some authors are devoting their attention in this direction and Dr. Moxon's book is a useful addition to the list of books published on the subject. The book has been written solely from the patient's point of view.

In Chapter III the author has taken a good deal of trouble in trying to give a clear idea of the metabolism in diabetes by comparing the human body with a motor car engine. He has first of all compared the human body in health with a perfectly working engine, in order

to make non-medical men understand exactly what goes wrong in diabetes. He has compared the carbohydrates, fats and proteins (to some extent) in the diet with the petrol in the motor car engine. Regarding the inherent property of the human system for the repair of the daily wear and tear of the tissues through the protein foods, there can be no comparison with the motor car engine because there is no mechanism there to repair the wear and tear due to use.

In this way the author has explained how combustion of the food takes place in the human body and how we get the calories that we require from the food we eat.

In Chapter IV the author has described how the human engine works in diabetes. For the smooth working of the motor car engine, there must be (1) a proper mixture of gasoline and air and (2) the ignition must be proper, because unless the sparking plugs are in working order to give a good electric spark it cannot ignite the mixture of gasoline and air. This function, in the author's opinion, goes wrong in diabetes. The spark or ignition has been compared to insulin and it is due to the loss or deficiency of this substance in the diabetic subjects that the proper combustion of carbohydrate food cannot take place.

The treatment of diabetes is described in simple language in Chapter VII, and in Chapter VIII the author describes how meals should be arranged for diabetic patients. The patient gets a fixed amount of carbohydrate, protein and fat for the day and he must choose a suitable diet and divide it into 2 or 3 meals and remain contented with that. The homely example which the author has given, such as a husband fixing a certain amount of money for his wife's dress and telling her that she can get whatever she wants so long as she keeps within the amount fixed for her, though quite appropriate, is not always practical. We are afraid that the average wife always tends to get round the husband and obtain whatever she wants even though "the husband absolutely fixes £15 for her hat, dress, and coat." We do not want the average diabetic patient to follow the wife's example and coax the doctor to give more than the doctor has actually prescribed for him.

Chapter X describes the general care of diabetic patients and Chapter XI describes insulin treatment. The last chapter describes the ordinary useful urinary tests which the patient can carry out himself.

The appendices are useful. No. 1 gives food value tables and No. 2 gives some very useful recipes for patients on a diabetic diet.

We feel sure that the book will be found useful by persons suffering from diabetes, because its perusal will enable them to follow their doctor's advice more intelligently and secure its fullest benefit.

J. P. B.

AN INDEX OF SYMPTOMATOLOGY.—By various writers. Edited by H. L. Tidy, M.A., M.D. (Oxon.), F.R.C.P. (Lond.). Bristol: John Wright & Sons, Ltd. 1928. Pp. 710 with 130 illustrations, some in colour. Price, £2 2s. net.

This volume forms an excellent companion to the *Index of Treatment*, the 9th edition of which was recently issued by the same firm of publishers. The former should be as popular as the latter has been; somehow one fears that it will not be. Symptomatology does not lend itself to indexing so well as does treatment. It cannot be said that diagnosis is actually more important than treatment; they are so completely interdependent—without the prospect of treatment a correct diagnosis would be pointless, and without diagnosis correct treatment would be impossible—but it is safe to say that diagnosis is more difficult than treatment, and that, therefore, the more we read on the subject the better.

The subjects dealt with in this volume cover a wide range: medicine, including tropical medicine, surgery—including special subjects—and gynaecology. There are about twenty-five contributors, some of whom deal with one or two, and others with many subjects. In most cases the writers are experts on their particular subject and are writing from wide practical experience in the several diseases with which they deal. The various

tropical diseases, which are naturally scattered throughout the book, are dealt with by one writer who is acknowledged as one of the leading experts on tropical medicine. This contributor has written on twenty-five different subjects. As it seems unlikely that any one man will have had much personal experience on more than about half these subjects, it seems that it would be better to have employed three or four contributors from different tropical areas to write on these very diverse subjects.

The volume should form an extremely valuable addition to any student's or medical man's library. The general arrangement of the book is very satisfactory, the printing and paper are excellent and the binding appears to be strong.

L. E. N.

NUTRITION IN HEALTH AND DISEASE FOR NURSES.—By Lenna F. Cooper, B.S., M.A., M.H.E., Edith M. Barber, B.S., M.S., and Helen S. Mitchell, B.A., Ph.D. London: J. B. Lippincott Company. 1928. Pp. viii plus 574 with 102 illustrations. Price, 12s. 6d. net. Available from Messrs. Butterworth and Company (India), Ltd. Price, Rs. 9-6.

This is one of Lippincott's Nursing Manuals, to which the description of "complete, practical, standard" is given by the publishers. Though intended primarily for nurses, the book is really a very complete exposition of the science and art of nutrition and cooking. The chapters on the principles of nutrition are scientifically sound and commendably brief. The physiological aspects of nutrition and food-stuffs are clearly and interestingly expounded. Cooking, the sense of food, the making of hospital menus and dietaries, and the modifications of diets required in various diseases are described. Numerous recipes for all sorts of meals are given, and though some of these are peculiarly American, the majority could be made equally well in India. The illustrations in this part are good and appetising. There is a useful chapter on teaching and examination methods.

This book deserves a wide circulation amongst hospitals and nursing institutions, though of course the section on cookery refers only to European dishes. Like most American publications, the book is very well got up, the printing and illustrations being of a high standard.

A. D. S.

FOOD.—By Robert McCarrison, C.I.E., M.D., D.Sc., LL.D., F.R.C.P., Lieut.-Col., I.M.S., Director of Nutritional Research, Pasteur Institute, Coonoor, South India. Madras: Macmillan and Co., Ltd. 1928. Pp. vi plus 115. Price, As. 12.

COLONEL McCARRISON's work on nutrition is so well known that anything from his pen is assured of a ready welcome. The present book is a small publication intended for the masses of India in particular. It sets forth the main facts about nutrition in a clear and succinct manner, explaining the uses of food, the purpose and nature of the proximate principles, minerals and vitamins, and the sources of these amongst Indian foods. The nature and necessity of "balanced" diet is discussed and the faults of ordinary Indian, Anglo-Indian and European diets in India discussed, and means of rectification suggested. A useful table of the composition of Indian food-stuffs is given. The diagram of the "Food Star" is effective and striking. The book is dedicated to the "Children of India," the price extremely moderate (12 annas), and the proceeds of its sale are to be devoted to certain Indian charities.

We recommend the book strongly to all teachers, colleges, welfare centres and juvenile organisations.

A. D. S.

MALAY POISONS AND CHARM CURES.—By John D. Gimlette, M.R.C.S., L.R.C.P. Third Edition. London: J. A. Churchill. 1929. Pp. xiv plus 301. Price, 10s. 6d. net.

The third edition of *Malay Poisons and Charm Cures* has been thoroughly revised and partly rewritten. The Malayan lawyers and Civil Service men (for whom the

book is specially intended) will much appreciate this edition, for it will be a reliable work of reference whenever they are confronted with Malayan witchcraft and folk-lore.

This book is divided into two main parts. The first part, which presents a detailed account of the charms, spells and black art practised in the Federated Malay States will be of interest to general readers as well, inasmuch as this is full of fantastic ideas and curious myths. The whole section has been written in a very pleasant and attractive style, in fact it reads more like a novel than a piece of serious literature.

The second part is of real scientific interest. It contains a collected account of the various poisons from the animal and the vegetable kingdom which the "bomor" or the "Malayan medicine man" deals with. There is much valuable information in this section for the pharmacologist and the pharmaceutical chemist. The nature and active principles of some of the poisons mentioned in the text have been partly worked out; but there is still a wide field for research in Malayan poisons and medicines.

Appendix at the end of each chapter is a feature of note. Appendix No. 2, which gives a tabular classification of the poisonous plants with their natural orders, also needs special mention for it will be of use to botanists.

R. N. C.

A REPORT ON THE LEAGUE OF NATIONS INTERCHANGE OF HEALTH OFFICERS IN INDIA.—By Dr. A. L. Hoops, M.D., D.P.H., B.A., Principal Medical Officer, Straits Settlements. London: John Bale, Sons & Danielsson, Ltd. 1928. Pp. 80. Price, 5s. net.

This is a report on the League of Nations interchange of health officers in India which followed the Far Eastern Association of Tropical Medicine Congress in Calcutta in December 1927, when a party of medical officers of health from other countries toured India under the auspices of the Government of India, inspecting general public health measures, hospitals, medical and research institutions, and medical education. It will interest the medical reader in India as a bird's-eye-view from the outside of what is going on in this country; but, as Dr. Hoops himself says, India is so vast that it is difficult to give a comprehensive review of even the medical and public health activities in this country.

Chapter I deals with population, agriculture and industries; Chapter II with the evolution of the Indian Medical Service and its present organisation. The present organisation of public health services in India is then considered, and an account given of the Indian Research Fund Association and the medical research institutes of India. Medical education is dismissed in two pages, but the Calcutta School of Tropical Medicine receives a chapter of four pages to itself. Hospitals and dispensaries in various provincial capitals are described, with photographs—which are unfortunately not labelled. The Mental Hospital at Ranchi is fully dealt with, and next comes a chapter dealing with the Indian prison system.

The rest of the report is given up to a miscellaneous series of subjects: leprosy in India; the sanitation of religious fairs and festivals; rural public health and the individual; irrigation and public health; the Asansol coal mines and their Board of Health; the work of the Kala-Azar Commission in Assam; the sanitation of New Delhi; malaria on the Assam tea estates; coolie immigration in Ceylon; voluntary Indian health and self-help organisations; and an account of the Mysore medical department.

We suppose that this report is of an official character. It has its interest for the medical reader in India, but we could wish that the subject had been dealt with in more detail. A book dealing with the whole subject of medical relief, medical education, medical research and public health in India is badly wanted. To some extent the *Souvenir on the Indian Empire*, published in connection with the Far Eastern Association of Tropical Medicine Congress, 1927, attempts this, and is

far more interesting reading than Dr. Hoops' report; but there is scope for a still larger publication, written by joint authors with many years' experience of work in India and of India's problems.

R. K.

CHRONIC (NON-TUBERCULOUS) ARTHRITIS: PATHOLOGY AND PRINCIPLES OF MODERN TREATMENT.—By A. G. Timbrell Fisher, M.C., F.R.C.S. (Eng.). London: H. K. Lewis and Co. 1929. Pp. xii plus 232. Illustrations 186 contained in 93 plates and the text. Size Demy 8vo. Price, 25s. net.

MUCH literature has accumulated round the subject of chronic arthritis and yet the ordinary student and practitioner feel that they are not much the wiser! Too much has been made of certain accepted theories, as that of infection from chronic septic foci, without adequate proof in many cases; in other instances we have not even a theory to comfort us.

This work is welcome because the author approaches the subject from the basis of definite experimental research into the physiology and pathology of joints; in the past these have been greatly neglected. One aspect has not been sufficiently studied in this book, the climatic and other considerations which are responsible for the undeniable fact that most forms of chronic non-tuberculous arthritis are very much less in evidence among the inhabitants of warm and tropical countries. How much the climate has to do with this, and how much the manner of living, are well worthy of study.

Various classifications are suggested: a subdivision into chondro-osseous, synovial, and mixed; or a modified grouping into proliferative (rheumatoid arthritis) of synovial or mixed type, and degenerative (osteo-arthritis) of chondro-osseous and mixed type. When an infective or traumatic cause is known to exist, these can also be indicated. The differential diagnosis of arthritis in a tabulated form, as given in the *Ministry of Health Report, No. 52*, is referred to: rheumatoid arthritis, osteo-arthritis, climacteric arthritis, and gout.

The author makes an appeal for team-work in special clinics, to work out the various clinical and pathological findings in large series of cases. A chapter is given to etiology, and one to symptomatology, while a full description of the recognized methods of treatment occupies the last chapter under the headings of medical treatment, physiotherapy, manipulative and orthopaedic measures, and surgical treatment.

Although we are still far from reaching a really satisfactory stage in our powers of diagnosis and treatment of chronic joint affections, our knowledge is definitely advanced by the author's work. The student and practitioner will welcome a book which deals with a difficult subject in a clear manner and which marks a definite advance in our knowledge.

F. P. C.

SUBSTANDARD LIVES AND THEIR ASSESSMENT IN LIFE ASSURANCE.—By Jehangir J. Cursetji, Medical Director, Oriental Government Security Life, Bombay. Pp. 66. Price, Re. 1-8 in India, 3s. 6d. in Great Britain and British Dominions, and 1 dollar in the U. S. A.

Substandard Lives and their Assessment in Life Assurance by Dr. Jehangir J. Cursetji, Medical Director to the Oriental Life Co., is a very interesting publication, and one which will be of considerable value to all who are interested in life assurance work.

The book is well arranged and the busy examiner can readily obtain the information he requires by referring to the list of contents and noting which chapter deals with defects in the system he is interested in.

Chapter VI on defects in the genito-urinary system is likely to be particularly helpful to examiners, but it is rather surprising that in dealing with the subject of albuminuria the author makes no reference to kidney efficiency tests.

Throughout the book frequent references are made to the opinions of European and American physicians, and one cannot help thinking that a more frequent expression of the author's own opinion would be of

greater value; he must be in a position which gives him immense clinical experience in life assurance work, and also he probably has access to the Oriental records, from which very valuable statistics on substandard lives could be obtained.

On p. 36 he quotes Dr. Kinnier Wilson as stating that the risk of injury or of death in an epileptic fit is altogether minute. Some of us however have probably had experience of death due to injuries received during the fit, and in the present day with roads in their congested and dangerous condition it seems that this risk is likely to increase.

In Chapter II under blood pressures no mention is made of diastolic pressures; it is always difficult for an examiner to assess cases of high diastolic pressures, and also it would be very interesting to know what are to be considered normal blood pressures for Indians; it seems probable that they are normally lower than for Europeans, also possibly the normal pulse rate for Indians should be taken at a higher rate than the standard 72 per minute for Europeans.

In making his recommendations for loadings, the author frequently states that an addition of a certain number of years should be added to the age, but the severity of this loading would vary with the age of the proposer; for instance a man aged 20 years with a loading of three years would get off much more lightly than a man aged 40, with the same addition to his age.

The proofs do not seem to have been very carefully revised: on p. 13 we find aortic "observation" instead of "obstruction," and on p. 57 "cholecystectomy" has been repeated, where "cholecystotomy" is obviously meant in the second case.

In conclusion, the author very rightly states that it is exceedingly difficult to assess substandard lives. This difficulty will always remain in India until more data are available, and until then all recommendations must be to a certain extent empirical. American methods of debit and credit have certain advantages, but they only supplement the clinical acumen of the examiner. What is really needed are statistics compiled from companies' Indian death claims. Very little original work has been done on Indian risks, and it is hardly fair, either to Indian proposers or to Companies operating in India, to judge their cases from European standards.

E. H.

Annual Reports.

ADMINISTRATION REPORT OF THE BALUCHISTAN AGENCY FOR 1927-28. CALCUTTA: GOVT. OF INDIA CENTRAL PUBLICATION BRANCH, 1928. PRICE, RS. 6-4-0.

THERE are certain items of medical interest in this report, mostly submitted by Lieut.-Col. L. J. M. Deas, I.M.S., Residency Surgeon and Chief Medical Officer. There were 42 hospitals and dispensaries working in the year as against 41 in the previous year; 604,053 patients were treated during the year; in-patients numbered, 12,191; whilst it is noted that the Church Missionary Society continued to do excellent work during the year. Tuberculosis is a problem in the Agency—most of the cases being imported from the Punjab or from Sindh, and the question of building a tuberculosis institute is under consideration. Operations performed numbered 17,274, whilst smallpox is so trivial a problem in the Agency that only 51 cases occurred during the year. An X-Ray Department and touring motor dispensary carried out good work during the year.

The Jail Department records a healthy year on the whole. The daily average number of prisoners was 426.6. The construction of a central jail for the Agency at Mach has been sanctioned and work on it was commenced during the year. In the meantime there is considerable overcrowding, and this had to be met by the transfer of some long time prisoners to such distant

provinces as Ajmere, Hyderabad Deccan, Bareilly and Cannanore. The average expenditure on guard and maintenance per head was Rs. 211-7-6. At the district jails at Sibi and Quetta blankets and cotton clothing are manufactured by the prisoners.

SIXTY-SIXTH ANNUAL REPORT OF THE GOVERNMENT CINCHONA PLANTATIONS AND FACTORY IN BENGAL, FOR THE YEAR 1927-28. By C. C. CALDER, SUPERINTENDENT, ROYAL BOTANIC GARDEN, CALCUTTA AND OF CINCHONA CULTIVATION IN BENGAL. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1928. PRICE, INDIAN, 13 ANNAS; ENGLISH, 1s. 3d.

THIS annual report is always of interest, despite the array of statistical figures presented, as it summarises the quinine situation in India. During the year the Linlithgow Commission took evidence on the agricultural state of India, and their recommendations with regard to cinchona cultivation in India, whether it is to remain a provincial subject, as at present in Bengal and Madras, or to become an imperial department will be awaited with interest. The problem obviously affects all-India, and the department should obviously become an all-India one, whilst the gravest problem to be faced is the finding and opening up of new areas suitable for cinchona plantation.

India's annual consumption of Government quinine totals about 60,000 lbs. whilst the reserve stocks in hand amount to over 400,000 lbs. This situation is not satisfactory, because it is obvious that much more quinine must be consumed in India if malaria in this country is to be controlled effectively. "Old established and reputable firms who formerly counted their sales in thousands of pounds saw them dwindle to hundreds, and could buy quinine on the market cheaper than they themselves were allowed to sell. Everything at present points to over-production if the effective demand only is thought of, and yet there is the realisation that the whole world's annual supply could be absorbed by India alone if the price was such as allowed of a ready sale," comments the report.

At Mungpoo climatic conditions were normal during the year, and the acreage was considerably increased. The average yield per acre was 3,264 lbs. Here, however, increasing difficulty is encountered in recruiting local labour, and the problem of recruiting local labour in the Darjeeling district will have to be faced. At Munsong an acutely epidemic disease affected the young seedlings, and is probably of fungoid origin. This infection chiefly affects younger plants and to some extent spares the well established ones. Labour difficulties have increased in this area also. "It would seem that the time is approaching when Government should become the direct employer of labour on these plantations." The harvest here was confined to thinnings and to the extraction of those trees which had died or had become unhealthy.

As a whole, the total acreage under cinchona plantation amounts to 3,161 acres, but forestry problems affect the cinchona yield. The total production of quinine sulphate (including that from imported Java bark) amounted to 46,845 lbs., and the total products, exclusive of converted products, was 58,371 lbs. No less than 95.5 per cent. of the available quinine in the bark was extracted—a very satisfactory figure. A new fire-proof building is being erected to store the increasing reserve of quinine held by the Government of India.

The following are further statistical details from the report:—

Year's expenditure, Rs. 2,57,378.

Harvest return for the year, Rs. 3,78,593.

Cost per lb. of quinine extracted from bark, Rs. 4-8-0.

Cost of extraction of quinine sulphate, Rs. 2,721 per lb.

Total cost of quinine per lb., extraction and manufacture, Rs. 7,521 per lb.

Wholesale selling rate of quinine per lb., Rs. 18.

Quinine sold during the year, total, 19,628 lbs.

Total receipts of the department, Rs. 5,38,202.

Total expenditure of the year of the department, Rs. 4,48,244.

Total earnings for the year, Rs. 5,80,520.

Provincial reserve of quinine at end of the year, 42,241 lbs.

Total value of stock carried over at end of year, Rs. 5,56,563.

It is to be noted that, in spite of a reduction in the selling rate of quinine tablets, the amount sold during the year was less than in former years; "the effective demand" concludes the report, "is only loosely connected with the price."

There were several changes of staff during the year; Mr. G. H. Fothergill is singled out for his excellent work as Assistant Manager, Munsong, during the year; and Mr. Thomas for sound management of the plantation under his immediate charge. Harkman Lama, overseer on the Mungpoo plantation and the oldest officer in the department, went on leave pending retirement, and it is noted that his retirement will be a serious loss to the department.

UNIVERSITY OF CALCUTTA. REPORT ON THE STUDENTS' WELFARE SCHEME (HEALTH EXAMINATION), FOR THE YEAR 1927. CALCUTTA UNIVERSITY PRESS, 1928.

THIS report deals with conditions which are now unfortunately only too familiar. During the year the committee investigated the conditions of students in four colleges, the Bangabasi College, the Post-Graduate classes, St. Xavier's College and Ripon College; and examined 2,161 students. Their complete data to date are based on the examination of a total of 14,866 students; and the committee report that they now consider that attention should be paid to the improvement of the health of students rather than to investigation into their state of health. Owing to financial difficulties the University is able to employ only one after-care officer, and at present the department can do little more than issue defect cards to students who are found to be suffering from any disease or are deficient or abnormal in any respect.

The number of students who are defective or diseased totals the appalling figure of 71 per cent., and only some 29 per cent. of students can be said to be really healthy. Defective vision affects 32.6 per cent.; and of these 63 per cent. are not provided with the necessary glasses; uncorrected vision is a most serious handicap to a student and we are glad to learn that the committee has taken special steps to have cheap glasses in nickel frames provided at concession rates by Messrs. B. K. Paul & Co. and the Sun Optical Co. Dental caries affects 8 per cent. of the students, whilst 18 per cent. suffer from bleeding and spongy gums, and a further 4 per cent. from pyorrhœa. A dental clinic is badly wanted, but funds for this cannot be provided.

An interesting report, based upon the above wide range of figures, is given for the normal average Bengali student. He is about 66.4 inches in height, 112.2 lbs. in weight, with chest measurements of 33.1 and 31.4 inches. The cephalic index is 80.1, and he is brachycephalic. The hand grip as measured by Smedley's dynamometer is 39.19 kilos for the right hand, and 36.33 kilos for the left hand. The students at the Presidency, Scottish Churches', and St. Xavier's Colleges are above the average general standard; those of the other colleges below.

That there is a vital need for compulsory physical training of university students in Calcutta is clear, and this matter is at present under the consideration of the Bengal Legislative Council. During 1927-28 the University allotted Rs. 17,000 to different colleges for such training, and Capt. P. K. Gupta, I.M.S. (retd.), gave thirteen lectures to students on physical culture. The Rowing Club showed an average daily attendance of 22 members, whilst swimming is practised in the Deshabandhu Tank, Shambazar. The model dietary drawn up by Rai Chunnilal Bose Bahadur was circulated to the heads of all hostels in Calcutta and the *mofussil*, but difficulties were experienced in introducing it. The

average cost is from Rs. 13 to Rs. 15 p.m., and many students are disinclined to change their habits.

This report tells of good work done, but it also shows the grave necessity for much further effort.

FIFTY-THIRD ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, BENGAL, FOR THE YEAR 1927. CALCUTTA: BENGAL SECRETARIAT BOOK DEPOT, 1928. PRICE, INDIAN, RI. 1-2; ENGLISH, 1s. 10d.

THE following is a brief résumé of the more important items of interest in the 1927 Report of the Chemical Examiner's Department, Bengal.

In the year under report 7,557 articles were examined in the department as against 7,021 articles in the previous year. This shows an increase of 536 articles.

Of the 7,557 articles examined during 1927, 4,831 were for Bengal, 365 for Assam, 2,179 for Bihar and Orissa, 84 for Government of India departments, 31 for the Chief Inspector of Explosives in India, 1 for the District Magistrate of Rangoon, and 66 miscellaneous.

During the year under report the analyses of excisable drugs were taken over by this office on behalf of the Excise Department, Bengal, with effect from the 14th April, 1927, under the orders of Government. This work was originally carried out by the Chemical Examiner for Customs and Excise, Calcutta. The number of analyses carried out under this head amounted to 1,045.

Medical and Scientific.—Under this head work has been carried out in connection with the cholesterol content of normal blood for standardisation purposes and also on the cholesterol content of leprosy blood. Researches have also been made in connection with the estimation of antimony and in the preparation of activated cholesterol for leprosy treatment. The results of the work on cholesterol have been published in the *Indian Journal of Medical Research*, January 1928. All expenses in connection with this work have been met by a grant given by the Research Fund Association.

Opinion cases.—The following are some of the opinions recorded in some special cases referred to this department:—

- (1) Opinion regarding the fixing of limits for aconite, arsenic, cannabis indica, cantharidis, opium, etc., in medicinal preparations containing these drugs.
- (2) As regards the standards for the cholesterol content of blood and a satisfactory method for its estimation.
- (3) As to the physiological effect of the juice obtained from galchun or golainchi.
- (4) Questions relating to the loss of weight in samples of quinine sulphate by evaporation of the water of crystallisation.
- (5) Questions relating to testing of food-stuffs and common adulterants in ghee and mustard oil.
- (6) The relative merits of ether and chloroform for anæsthetic purposes with special reference to their keeping properties in a hot climate.
- (7) As to the cause of precipitation of strychnine in a bottle containing strychnine hydrochloride.
- (8) As to whether small quantities of osmic acid (osmium tetroxide) securely packed as per certain specific conditions, may be allowed to pass through the Inland Post.
- (9) As to how the floor of a kerosene shed, heavily impregnated with this oil can be cleansed.

General Department (including Excise).

In the General Analytical Department 3,058 examinations were made as compared with 2,296 for the previous year; the increase is due to the transfer of the excise work to this department.

Of the above 3,058 examinations, 2,566 were carried out for Bengal, 66 for Assam, 277 for Bihar and Orissa, 74 for Government of India departments, 31 for Chief Inspector of Explosives in India, 1 for District Magistrate of Rangoon, and 43 miscellaneous.

Excise Branch (General Department).—This was opened on the 14th April, 1927. During the year under

review the following number of samples were dealt with by this section as well as by the General Department.

Cocaine.—Two thousand one hundred and seventy-eight samples of cocaine were examined during the year as compared with 1,460 for the previous year, showing an increase of 718 samples.

Of the above 2,178 examinations, 1,379 were carried out for the Excise Department, Bengal; 582 for the Presidency Magistrate, Calcutta; 8 for the Commissioner of Police, Calcutta; and 209 for Bihar and Orissa.

In addition to the examination for the presence of cocaine, a large number of the samples had to be assayed as to their fitness for medical use in accordance with the British Pharmacopœia specifications. Many of the samples were found to be grossly adulterated and none were found to conform to the British Pharmacopœia standards.

Opium.—One hundred and ninety-eight samples of opium were examined during the year as against 41 during the previous year, showing an increase of 157 samples. In addition to the detection of opium, practically all the samples had to be assayed for prosecution purposes under the Excise Act.

In connection with the above 198 samples, 175 examinations were carried out for Excise, Bengal; 17 for Excise, Assam; 4 for Excise, Bihar and Orissa; and 2 for the Opium Factory, Ghazipur.

The two samples from Ghazipur (provision opium) had to be assayed for moisture, ash, morphine, narcotine, codeine and water soluble extract at 100°C.

Preparations of opium.—Under this head 26 samples of chandu, 7 samples of imshi, 4 samples of kafa, 1 sample of morphia and 2 samples of "chlorodyne" and "camphorodyne" were examined.

Bhang and its preparations.—Eight samples of bhang, 5 samples of charas and 5 samples of modak were examined during the year under report. The physiological activity of these samples was assayed on cats.

Bakhar.—Thirty-three samples of bakhar were examined in the General Department and 16 were examined in the Medico-legal Section. This substance is largely used as a fermenting agent in the preparation of pachwai. Unfortunately several samples have been found to be contaminated with aconite, and fatal cases have occurred from drinking liquor fermented by this means.

Articles of food.—Under this head 18 samples of ghee were examined, of which only 6 samples conformed to the requirements of the Food Adulteration Act; 4 samples of butter of which 3 conformed; 4 samples of milk of which none conformed; and 15 samples of mustard oil of which 4 conformed to the Act.

Work under the head of food-stuffs is gradually diminishing since the establishment of the Public Health Laboratory. Cases on appeal will, however, have to be dealt with in this department.

Thirty-four samples of drugs were analysed during the year under report; practically all these analyses were undertaken for the Medical Store Depot, Calcutta, in connection with the British Pharmacopœia specifications of drugs for medical use.

Medico-legal Notes.

The following notes on medico-legal cases were supplied by Senior Assistant Surgeon Hiralal Sinha, B.A. L.M.S., who was in charge of the Medico-legal Department:—

Poisoning by carbolic acid (suicidal?).—The viscera of a European male, aged 70 years, were forwarded by the Medical Officer of Barrackpore with the history that the victim was found dead in bed in a garden. On post-mortem examination the mucous membrane of the stomach was found white and corroded but the Medical Officer could not give any definite opinion as to the cause of death. Carbolic acid and alcohol were detected in the viscera.

Poisoning by Arsenic.—(a) *Arsenic in a charred body.*—The Assistant Surgeon of Perojpur forwarded for examination a quantity of burnt and charred viscera said to be the remains of the stomach, liver, and kidneys of a Hindu female aged about 24 years, whose burnt body was removed from the funeral pyre by the police,

as she was reported to have committed suicide by poison. Arsenic was detected in the viscera. It may be noted that arsenic, though a volatile poison, has often been detected in partially burnt bodies and even in partially-burnt bones.

(b) *Arsenic (slow elimination).*—The Veterinary Assistant Surgeon of Mymensingh forwarded the viscera of a bullock with the history that the animal was alleged to have been poisoned on the 9th October and died on the 18th October. Arsenic was detected in the viscera. The case illustrates the slow elimination of arsenic from the system.

(c) *Homicide by arsenic and strangulation.*—The viscera of a male child, aged 3½ years, were forwarded by the Sub-Assistant Surgeon of Jamalpur (Mymensingh) who reported post-mortem signs of strangulation. The stomach was found empty and healthy and the intestines contained soft yellow faeces. Death was ascribed to strangulation but arsenic was detected in the viscera.

(d) A similar case was also forwarded by the Civil Surgeon of Bakarganj, the deceased being a Hindu female aged 16 years. There were post-mortem signs of strangulation and death was ascribed to strangulation by the Civil Surgeon. Arsenic was also detected in the viscera.

Strychnine poisoning from a quack remedy.—The Assistant Surgeon of Jorhat forwarded the viscera of two female children aged 3 and 5 years respectively with the history that their father gave them some powder alleged to have been supplied by a bhutia for worms. Soon after taking the powder both the girls began to struggle and had convulsions and died within half an hour. The medical officer could not give any opinion as to the cause of death. Strychnine was detected in the viscera of both.

Poisoning by nux vomica (in mistake for opium).—The Assistant Surgeon of Darrang forwarded the viscera of an adult female with the history that her husband brought some stuff from another person who alleged it was opium and it was taken by his wife. She soon developed symptoms of strychnine poisoning and died. Strychnine and brucine were detected in the viscera.

Atropine poisoning (fatal).—(a) The viscera of an unknown male found lying at a street crossing in Calcutta were forwarded by the Coroner of Calcutta, as the medical officer who performed the post-mortem examination could not give any definite opinion as to the cause of death. Atropine was detected in the viscera.

(b) **Drugging by atropine.**—The Commissioner of Police, Calcutta, forwarded the stomach washings of two women of the town and a small quantity of yellowish powder found in their room, with the history that three up-country young men visited them and offered them liquor, meat, puri, etc., brought from outside. Soon after taking the food they became unconscious and were removed to hospital where one of them died the next day, and the other recovered. Atropine was detected in the stomach washings of both as well as in the yellowish powder. The viscera and urine of the deceased were forwarded by the Coroner of Calcutta for analysis. No poison could be detected in the viscera but atropine was detected in the sample of urine.

Hydrocyanic acid in fodder.—The Veterinary Assistant Surgeon of Dinapur forwarded in the month of June the viscera of two buffaloes and a quantity of young green grass, said to be "Burroo grass," for analysis, with the following history:—Two animals out of a number of buffaloes and buffalo calves while grazing on the military grass farm at Dinapur became very ill, fell down, and died in a semicomatose state within half an hour from the onset of the symptoms. Hydrocyanic acid was detected in the specimen of the grass sent but no poison could be detected in the viscera of the two animals. Later in the season further samples of this "Burroo grass" were examined but no hydrocyanic acid could be detected. Identification of the plant was carried out by the Botanical Office and was found to be *Sorghum halepense Pers.* (vernacular *Barni, Kala Mucha*). Other cases though rare have been referred

to this department previously where young plants were found to contain hydrocyanic acid (probably a cyanogenetic glucoside).

Hydrocyanic acid poisoning (suicidal).—The viscera and urine of a Hindu male aged 22 years were received from the Coroner of Calcutta with a history that the deceased was found lying dead in his room, the door of the room being bolted from inside. The medical officer could not give any opinion as regards the cause of death. Hydrocyanic acid was detected both in the viscera and in the urine.

Croton poisoning (homicidal?).—The Deputy Commissioner of Police, Calcutta, forwarded the stomach washings of two brothers who felt a burning sensation in the stomach and started vomiting after taking some cooked dal and bread, which were also forwarded. They recovered after treatment in hospital. Croton was detected in the stomach wash of one and in the cooked dal.

Aconite poisoning (by taking liquor).—(a) A case of multiple poisoning by aconite was referred by the Deputy Commissioner of Police and the Coroner of Calcutta, with the following history. Ten people drank some liquor mixed with soda water from a bottle labelled "Beehive Brandy" which was purchased by one of them along with several empty bottles. They all felt an immediate irritation in their throats and they vomited. They were removed to hospital, where their stomachs were washed. Four, however, died. The viscera of the four deceased were forwarded by the Coroner of Calcutta together with the stomach washings of all of the ten victims; the bottle labelled "Beehive Brandy" with a portion of its contents, was forwarded by the Deputy Commissioner of Police, Calcutta, for analysis. Aconite was detected in the viscera of two of the victims and in the stomach washings of 8 of them as well as in the liquor labelled "Beehive Brandy."

(b) *Aconite poisoning (homicidal).*—The Sub-Assistant Surgeon of Rajbari, Faridpur, forwarded the viscera of a boy aged 12 years with the history that the deceased was offered by one of the "antiparty" some "Gazi's Sinni," on taking which he complained of tingling in the throat, pain in the stomach, and died after half an hour. Aconite was detected in the viscera.

Lieut.-Col. T. C. Boyd, F.R.C.S.I., D.P.H., F.I.C., I.M.S., held charge of the department during the year under review.

KING EDWARD VII MEMORIAL PASTEUR INSTITUTE AND MEDICAL RESEARCH INSTITUTE, SHILLONG. THE ELEVENTH ANNUAL REPORT FOR THE YEAR ENDING 31ST DECEMBER, 1927. LIEUT.-COL. J. MORISON, I.M.S., DIRECTOR. SHILLONG: PRINTED AT THE ASSAM GOVERNMENT PRESS, 1928. PRICE, 1s. 3d. or 13 ANNAS.

DURING the year 1,142 patients came for treatment; of these 1,100 cases were Indians and 42 Europeans. Sixty-four others were advised that treatment was unnecessary as the bite did not penetrate the skin or because the dog was not suffering from rabies 10 days after the bite. Eleven persons discontinued treatment of their own accord. No further information regarding them is available and these cases are not included in the statistics.

Four more cases developed hydrophobia during treatment. These 4 patients arrived 13, 20, 24 and 88 days respectively after being bitten. They form 26.7 per cent. of the total deaths from hydrophobia among persons coming to the Institute, an unusually high proportion. These deaths, though excluded from the general statistics, are important for they are an index of the accessibility or otherwise of an Institute. For example, when treatment was available only at Coonoor (the Pasteur Institute for the Madras Presidency) the deaths during treatment among 33,253 persons was 13.2 per cent. of the total mortality. After centres for antirabic treatment had been established throughout Madras, the deaths during treatment among 19,263 persons fell to 6.3 per cent. of the total mortality. Though deaths

during treatment are not an index of the efficacy of the treatment itself, it is important that they be not overlooked as our aim should be to make the treatment so accessible and so thoroughly appreciated that the only deaths during treatment are those exceptional cases who develop the disease less than three weeks after the bite.

The number of patients treated this year is 275 less than during the previous year.

Of the total, 1,106 persons came from Assam and 36 from Bengal.

Out of the 1,142 persons who were treated reports have been received from 1,110. These reports should be sent to the Institute on post cards three months after the completion of treatment. In 305 instances the information did come soon after the lapse of three months, but in 805 cases the information was sent much later—from 4 to 13 months after treatment; each case failing to report had been followed up. We have failed to get information in only 32 cases or 2.8 per cent. of the total.

Among the 1,142 cases there were 11 deaths, giving a mortality of 0.96 per cent. The number of failures, that is to say, patients dying of hydrophobia subsequent to 15 days after the conclusion of treatment, is 6, giving a failure rate of 0.52 per cent.

The proportion of persons licked on scratches and abrasions is small. In this class came 26 Europeans and 44 Indians or 0.61 per cent. of the whole. A superficial bite in some Institutes is interpreted as a bite which does not penetrate the skin. The drawing of blood is evidence of penetration through the skin and the possible implantation of the virus in a region richly supplied by nerves and is sufficient to place the bite in the class of deep bites. In such Institutes the class of superficial bites is limited to scratches and abrasions by the teeth. In this Institute this rule does not seem to have been followed and superficial bites include numbers of bites which in other Institutes are classed as deep. This is one of the points on which uniformity of practice at various Institutes might be attempted. In our statistics for this year it happens that the definition of superficial and deep does not affect the mortality; for all the 11 fatal cases had really deep bites in the less technical sense.

A new feature in this year's statistics is the division of the Indian cases arriving during the first week into 8 classes those arriving on the day of the bite (0 days late) and on the 1st, 2nd, 7th day after being bitten. Among 1,100 Indians not a single case arrived at Shillong for treatment on the day of the bite. Out of 316 cases arriving during the first 4 days after the bite there was one death. Out of the 240 cases who arrived on 5th, 6th and 7th day there were three deaths. These four cases died in 25 to 31 days after being bitten and on them and on one other case arriving 10 days late and who died on the 38th day, there is no evidence that the treatment had any effect whatsoever. In the remaining six fatal cases the interval between the bite and the death was from 52 to 156 days. There is a gap of 14 days between the last of the first group and the earliest of the second group on whom possibly treatment had the delaying effect which was demonstrated by Lieut.-Col. McKendrick (sixteenth annual report, Pasteur Institute, Kasauli). The numbers are small but they illustrate a feature of antirabic treatment of which two explanations have been given (a) that in the first group the virus has been at once planted in a nerve where it is shielded from the action of the protective bodies generated by the treatment, and (b) that there are strains of virus against which the strain of vaccine used in a particular Institute has no effect. It is one of the grave handicaps of treatment at a remote Institute that it has hitherto been impossible to investigate these strains. It would be of great value if medical officers under whose care these fatal cases come would procure for us strains of the virus.

As the figures stand, however, they illustrate once again the benefit of early treatment; among 705 Indians arriving during the first week the mortality was 0.57

per cent.; among 395 arriving after the first week the mortality was 1.77 per cent.

This year among Indians only 98 were bitten through clothing; among these there were no deaths.

Excluding superficial bites and bites through clothing, 279 cases whose wounds had been cauterised had a mortality of 0.72 per cent. and 297 cases whose wounds had not been cauterised had a mortality of 3.03 per cent.

A feature of the cases arriving at Shillong is the number of cases arriving with large septic sloughing wounds. Such wounds were rarely seen at the Pasteur Institutes of Bombay and Rangoon which draw their cases very largely from near at home, but they are also a feature of the cases at another hill Pasteur Institute (Kasauli). They are not due to the special severity of the bites coming to this Institute but to the inadequate dressings these bites receive before they are sent on their journey and the enforced neglect during the period, often extending for a week or more, when the patient is trying to get here. Small deep tooth marks are not efficiently cleaned and dressed. After cauterisation, if this is done, the wound may not bleed and gives no indication of the extensive sloughing that may follow the implanted septic infection. Every tooth mark or wound small or great that is cauterised should be carefully dressed.

In only two cases was a jackal bite fatal. Five out of 11 fatal cases were children of 7 years and under.

Owing to the success attending the treatment of kala-azar by antimony compounds in the plains and the number of centres for such treatment which Government has established, the cases which now come to this Institute are doubtful cases for diagnosis and cases which have resisted the treatment administered elsewhere. The emptying of the experimental ward for kala-azar, crowded to overflowing less than two years ago, is itself a tribute to the usefulness of this ward and the success of the investigations carried out by former Directors. It is very desirable that the ward should now be open for cases with diseases other than kala-azar, e.g., chronic dysentery and sprue, on which researches are now being carried out.

The total number of routine examinations was 2,512 as against 2,948 in 1926. For a province like Assam too little use is made of the Wassermann reaction for syphilis, a test essential for the diagnosis and adequate treatment of the disease.

Throughout the year the Institute has distributed prophylactic vaccine for influenza, enteric fever and cholera prepared by the Central Research Institute, Kasauli. The following amounts were issued.

Influenza	23,480 c.c.
T. A. B.	3,580 "
Cholera	4,19,380 "

The demand for cholera vaccine was so great and at times so urgent that the Government of Assam at the close of the year requested this Institute to resume its manufacture.

Correspondence.

SUDDEN DEATHS IN YOUNG FEMALES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I should be much obliged if any of your readers could enlighten me on the following points:—

(i) Whether sudden deaths from heart failure are common or likely among young female patients of age 16 to 25; whether such deaths can occur at any time, day or night, during waking or sleeping hours; whether anaemia in such women can be a cause of sudden and immediate death by causing cardiac, cerebral, or pulmonary emboli; or whether a sudden attack of angina pectoris can cause sudden death in such a type of patient? Any reference to standard works of medicine would be welcome.

(ii) Whether it is the duty of medical men to report all cases of sudden deaths—whether due to natural causes, as well as those due to unnatural causes—to the police authorities; or only such cases of sudden death in which poisoning is suspected, or where the true cause of death is in doubt?—Yours, etc.,

C. G. MAHADEVIA, M.B., B.S.

JERMAHAL, BOMBAY,
POSTAL DISTRICT 2,
27th November, 1928.

[Note.—Rupture of an ectopic gestation might lead to such a sudden death, perhaps.—EDITOR, I. M. G.]

THE STERILIZATION OF SYRINGES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I should be much obliged if any of your readers would let me know through your columns of any suitable, but safe and surgically reliable, technique for the best method of keeping "Record" hypodermic syringes and needles so that they may be instantly available at the bedside for immediate use without previous sterilization.

Do you consider the following method of sterilization safe with regard to asepsis?—viz., a small quantity of rectified or methylated spirit is drawn up into the syringe through the needle and then ejected, repeating the process say five to ten times? If not, will you please suggest any simple method (other than boiling) which will effectively sterilize both syringe and needle for immediate use in the emergencies of a busy practice at the bedside?—Yours, etc.,

JYOTI DHUR ROY, B.Sc., M.B.

ALIPORE P. O.,
CALCUTTA.

4th February, 1929.

[Note.—We have known doctors to keep their hypodermic syringes, with the parts taken apart, permanently in a solution of 1 part of lysol in 9 of rectified spirit, and then rapidly to rinse the syringe through with rectified spirit to get rid of the lysol before using it; but whether such a procedure could be relied upon to get rid of spore-bearing organisms is doubtful.—EDITOR, I. M. G.]

SUBCUTANEOUS INJECTION OF OILS OR OILY PREPARATIONS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It is said that any oil when injected subcutaneously is hardly absorbed at all. Hence camphor in oil is not of much use when so injected.

Is it the same case with oil of hydnocarpus when infiltrated subcutaneously? If so, can one expect any very good result from subcutaneous injection of oils, or oily preparations?—Yours, etc.,

A. F. W. DACOSTA, F.R.C.S., D.T.M., I.M.S.,
Civil Surgeon.

BILASPUR, C. P.

Dated the 25th January, 1929.

[Note.—When camphor is given rapid stimulation is usually required; for this camphor in oil is unsatisfactory. In the case of hydnocarpus oil such rapid absorption is not necessary. Dr. E. Muir informs us that absorption of this oil takes place in 3 days to 2 weeks.—EDITOR, I. M. G.]

A SIMPLE RAT TRAP.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I think that the following method of rat trapping may be of some interest to your readers as it is extremely simple and effective.

The top is removed from a kerosene tin which is then sunk in the ground so that the top of the tin is flush with the ground level. The tin is then half filled

with water. This is all that is necessary. The rats in their efforts to get to the water, fall into the tin and cannot get out. By this means 2 to 5 rats per tin per night have been caught in this district. As soon as the nightly catch fails, which it usually does in 4 to 5 days, the site of the tin is changed.

Tins should be sunk in places where other supplies of water are not readily available, and the tops of the tins may be camouflaged with leaves or straw.

The advantages of this very simple method are: that the materials are available in any village, the method is fool-proof, no bait is required, tins need not be handled, the rat fleas are immobilised if not drowned, and the kerosene tins are cheaper than traps.

The method was first introduced by Dr. K. A. T. Martin in South Africa, but as it does not appear to be known in India, I thought some of your readers might care to try it.—Yours, etc.,

C. J. STOCKER, MAJOR, I.M.S.
Civil Surgeon.

HOSHANGABAD,
25th February, 1929.

A CASE OF ACUTE VAGINISMUS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Will you or any of your readers kindly suggest any practical way of treating the following condition?

I have a patient who is a young Bengali girl of 20 quite healthy and robust. She was in love with a healthy young man, whom she married some two years back. Both the husband and the wife deny a history of even a single act of successful coitus, since their marriage. This being a very obstinate case of vaginismus, I have carefully gone into the history of the case but have failed to elicit any fact to prove that the vaginismus was due to ignorance on the part of the husband or due to any psychical factor. Both the husband and the wife are fairly educated and are of "advanced views." Any attempt at examination per vaginam without complete surgical anaesthesia is impossible. A gynaecologist was consulted who examined the patient under chloroform anaesthesia. The vagina was found to be fairly dilatable and no local abnormality could be found. The vagina was dilated several times under chloroform anaesthesia without any effect. Cocaine suppositories could not be inserted (without surgical anaesthesia) on account of the acute vaginismus. Textbooks suggest that pregnancy may cure it. But how is it possible to bring about pregnancy in this case?—Yours, etc.,

ACCIDENTAL SUFFOCATION IN A WELL.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following particulars of the accidental deaths of five persons from suffocation in a newly constructed well may be of interest to your readers. I held an official investigation into the circumstances under orders of the Inspector-General of Civil Hospitals, Bihar and Orissa, and the report is dated the 6th July, 1928.

The well was situated in the village of Dhananti, near Sewan in Saran District. It had been under construction for some three months when the accident occurred. First a pit some 10 feet deep was sunk, then the well was commenced at the bottom of this pit, and had been sunk to a depth of about 20 feet, making some 30 feet below the surface in all; masonry work, consisting of burnt brick and clay had also been applied to a height of about 16 feet. A working gang of six persons had been at work daily for a fortnight on the well without accident.

On the afternoon of the 24th June, 1928, a boy aged 14 or 15 years was sent down to the bottom of the well to

bring up an iron implement which had slipped. The depth of water in the well at the time was about 4 feet. The boy suddenly became suffocated and died (his body being subsequently found standing upright with the water reaching only to his shoulders)... The rope to which he was tied broke.

A second individual next went down the shaft of the well with a rope to try and rescue the boy, but was suffocated and dropped into the water. A third then went down, dangled his legs in the water and tried to grasp the two still living bodies between his knees. He suddenly felt suffocated, however, and shouted to be drawn up. This man recovered; he states that he thinks the two were still living when he tried to pick them up, but that the water smelt horribly, and that he was in imminent danger himself of suffocation. Two other men followed him in turn down the well in an attempt to rescue the first two; but both became suffocated and dropped into the water. A sixth man was lowered into the shaft, but found himself suffocating when within a few feet of the surface, and shouted to be drawn up. This man was the second of the two survivors.

The well was sunk inside a walled-in yard, the enclosure walls being about 5 feet high, and with rooms on one side of the courtyard. Persons living in these rooms have not been affected at any time. Within 20 feet of the pit in the enclosure is a feeding platform for bullocks; these bullocks being still well. The site of the well had previously been used for collection of rubbish, whilst a saltpetre manufacturing godown at one time existed on the site. Fourteen years previously a brewery existed about 120 yards from the well, and there is a burial and burning ghat for Hindus about 200 feet west of the well.

On approaching the well, one noticed a strong smell of sulphur, and gas was seen to be actively bubbling up from the water in the well. Post-mortem examination on the five bodies was conducted by Assistant Surgeon M. N. Pal of Sewan some 24 hours after death, and he came to the conclusion that death was due to suffocation from poisonous gases, and not drowning. In each case dark red fluid blood was found in the right side of the heart, cyanosis was present, and in the stomach coffee-ground-like substance. In two of the bodies water was also present in the stomach, but death does not appear to have been due to drowning.

An empty hydrogen peroxide bottle was lowered into the well in the hope that the gases present would displace the air in it; the bottle was left *in situ* for fifteen minutes, then drawn to the surface quickly and immediately sealed with the special air-tight stopper used for hydrogen peroxide bottles. A second similar bottle was filled with water from the well, and similarly sealed. These samples were sent to the Chemical Examiner at Calcutta.

Three coins—a silver rupee, a nickel one anna piece, and a copper pice—were placed in the bottom of a bucket of water drawn from the well for ten minutes. All three showed a black coating, evidently a sulphide. These were also forwarded to the Chemical Examiner.

The Chemical Examiner reported that sulphuretted hydrogen gas in quantity was detected in the bottle of water withdrawn from the well; and carbon dioxide was detected in the bottle of air from the same source. The black stains on the three coins were due to the sulphides of the respective metals concerned.

I have not been able to find out how the water of the well became so intensively contaminated with sulphuretted hydrogen, but the surroundings of the shaft were anything but satisfactory from a hygienic point of view. The well was filled in with earth and has never been reopened.

My thanks are due to Colonel Willmore, I.M.S., Inspector-General of Civil Hospitals, Bihar and Orissa, for kind permission to publish these notes on the occurrence.—Yours, etc.,

RAJESWAR PRASAD, I.M.S.,
Assistant Surgeon.

ARRAH,
22nd February, 1929.

A CASE FOR DIAGNOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—With reference to the case for diagnosis reported on p. 118 of your issue for February 1929 by Dr. M. D. Pillai, I think the case to have been one of calcium deficiency. The unconsciousness, clenched teeth, closed eyes, etc., are manifestations of tetany. An injection of adrenalin, instead of digitalin and strychnine, might have fixed the calcium ions. Parathyroid and calcium by the mouth might have restored the calcium metabolism to normal. Unless such measures are taken there may be a chance of a recurrence of the symptoms in the patient.—Yours, etc.,

CH. KRISHNAMURTY, L.M.P.

CENTRAL JAIL, RAJAHMANDRY,
28th February, 1929.

A CASE FOR DIAGNOSIS. CORRIGENDUM.

[In connection with the above case, reported on p. 118 of our issue for February 1929, Dr. Pillai has asked us to publish the following corrigendum; line 17; in place of 'with my consultation,' please read 'without my consultation.' Line 30; instead of 'Tinct. hyoscy. 5ss.' please read 'Tinct. hyoscy. 5ss.'—Ed., I. M. G.]

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel W. J. Powell, M.D., I.M.S., Inspector-General of Prisons, Central Provinces, is appointed to officiate as Inspector-General of Civil Hospitals, Central Provinces, in addition to his own duties, with effect from the 21st February, 1929, and until the date on which Lieutenant-Colonel W. V. Coppinger relieves him of the additional duties.

Lieutenant-Colonel W. V. Coppinger, D.S.O., M.D., F.R.C.S.L., I.M.S., Professor of Ophthalmic Surgery, Medical College, Calcutta, is appointed to officiate as Inspector-General of Civil Hospitals, Central Provinces, vice Colonel Norman Walker, with effect from the date on which he assumes charge of his duties. He will be appointed permanently to that post, with effect from the 30th March, 1929.

Lieutenant-Colonel C. A. Sprawson, C.I.E., M.D., F.R.C.P., V.H.S., I.M.S., Principal and Professor of Medicine, King George's Medical College, Lucknow, is appointed to be Inspector-General of Civil Hospitals, United Provinces, with effect from the 16th March, 1929.

Lieutenant W. L. Neal, I.M.S., Military Medical Officer at Gyantse, is appointed to officiate as British Trade Agent, Gyantse, and as British Trade Agent, Yataung, in addition to his other duties, with effect from the 1st March, 1929, and until further orders.

LEAVE.

In supersession of the previous notification, Major-General F. H. G. Hutchinson, C.I.E., M.B., K.H.S., I.M.S., Surgeon-General with the Government of Madras, is provisionally granted, preparatory to retirement, leave on average pay for 8 months combined with leave on half average pay for 18 months and 25 days, with effect from the afternoon of the 2nd August, 1928.

Colonel J. Norman Walker, M.R.C.P. (Lond.), I.M.S., Inspector-General of Civil Hospitals, Central Provinces, is granted leave preparatory to retirement for 6 months and 8 days on average pay, with effect from the 21st February, 1929, or the date on which he avails himself of the leave.

Lieutenant-Colonel B. E. M. Newland, I.M.S., Civil Surgeon, Moradabad, leave on average pay for 6 months and 26 days, combined with leave on half average pay for 1 month and 4 days, total 8 months, with effect from 24th February, 1929, or the date of relief.

Lieutenant-Colonel R. S. Townsend, I.M.S., Civil Surgeon, Mussoorie, leave on average pay for 26 days

combined with leave on half average pay for 1 month and 17 days, total 2 months and 12 days, with effect from 20th December, 1928, or date of relief.

Lieutenant-Colonel J. F. Boyd, I.M.S., Civil Surgeon, on leave, has been granted by the High Commissioner for India a further extension of 3 months' leave on half average pay on medical certificate, in continuation of the leave sanctioned in Government Notification No. 1098[V—6, dated 26th October, 1928.

Lieutenant-Colonel E. S. Phipson, D.S.O., I.M.S., Health Officer of the Port of Aden, Medical Officer in charge of European General Hospital, and Civil Administrative Medical Officer, Aden, is granted leave for 7 months, with effect from the 1st April, 1929, or the subsequent date of relief.

In modification of Government Notification No. S. 20/10, dated the 28th January, 1929, Lieutenant-Colonel W. M. Houston, I.M.S., Health Officer of the Port of Bombay, is granted leave for 1 year, with effect from the 16th March, 1929, or the subsequent date of relief.

Major W. P. Hogg, D.S.O., I.M.S., an officiating Agency Surgeon, is granted leave on average pay for 3 months under the Fundamental Rules combined with furlough under the Military Rules for 5 months, with effect from the 1st March, 1929.

RETIREMENTS.

Lieutenant-Colonel F. W. Gee, C.I.E., M.B., I.M.S. (retd.), 18th August, 1928.

Lieutenant-Colonel W. R. Battye, D.S.O., I.M.S., with effect from the 20th January, 1929.

Lieutenant-Colonel A. W. Greig, I.M.S., with effect from the 29th January, 1929.

PROMOTIONS.

Major to be Lieutenant-Colonel.

Mozaffer Din Ahmed Kureishi. Dated 4th March, 1929.

Captains to be Majors.

B. Basu, F.R.C.S.E. Dated 5th February, 1929.

M. A. Jafarey. Dated 25th February, 1929.

G. Verghese, M.B. Dated 27th February, 1929.

A. D. Loganadan. Dated 27th February, 1929.

S. N. Mokand, M.B. Dated 1st March, 1929.

HONOURS.

His Excellency the Grand Master of the Most Eminent Order of the Indian Empire is pleased to announce that His Imperial Majesty the King, Emperor of India, has been graciously pleased to make the following promotions in, and appointments to, the said order:—

To be Companions.

Lieutenant-Colonel C. I. Brierley, I.M.S.

Lieutenant-Colonel R. E. Wright, I.M.S.

Lieutenant-Colonel H. H. Broome, I.M.S.

His Imperial Majesty the King, Emperor of India, has been graciously pleased to give orders for the following promotions in, and appointments to, the Most Excellent Order of the British Empire:—

To be Commanders.

Civil Division.

Lieutenant-Colonel J. K. S. Fleming, O.B.E., I.M.S.

NOTES.

CROOKES' LABORATORIES.

We are glad to report that Messrs. Crookes' Laboratories have recently opened up a branch depôt in this country. The "Collosal" and other products of this firm are well known, and are of truly colloidal character, whereas many "colloidal" products on the market are merely crude suspensions. The agent for India is Mr. J. L. Holden, M.P.S., c/o British Colloids, Ltd., The Crookes' Laboratories, 10, Graham Road, Ballard Estate, Bombay.

LANTERN SLIDES FOR PUBLIC HEALTH PROPAGANDA.

THE Calcutta Pure Drug Co., 4-1, Waterloo Street, Calcutta, have recently forwarded to us a copy of their revised catalogue of lantern slides for public health propaganda purposes. These slides are in sets, and will be of considerable interest to public health workers in this country. They include key-lectures with the following numbers of slides for each subject: malaria (24); kala-azar (19); cholera (22); small-pox (15); tuberculosis (28); leprosy (30); plague (36); beriberi (12); malaria fever and its causes (39); ankylostomiasis (sets of 12 and 28 slides respectively); school sanitation (12); venereal diseases (30); maternity and child-welfare (36); first aid (34); physical culture (39); and sets on temperance, agriculture and the dairy, natural science, and industries.

The prices are: for uncoloured slides Rs. 9 per dozen; for hand-coloured slides Rs. 12 per dozen. The same firm also stock lanterns and accessories.

LIVER EXTRACT B.D.H.

THE treatment of pernicious (and other forms of) anemia, and of sprue with liver extract dates from the cardinal work of Minot and Murphy in 1927. The following is an abstract of their chief paper (*British Med. Journ.*, 10th March, 1928), in which the treatment was tested on 34 patients, of whom 32 responded favourably to it.

The clinical trials made in various hospitals upon samples of liver extract distributed by The Medical Research Council were reported upon briefly in the *British Medical Journal* and *The Lancet* of March 10th, 1928. In these trials the extract was gauged by the rate of increase of the young red cells (reticulocytes). In practice it was found that simultaneously with this increase there was a distinct feeling of general improvement in the patient, and this was followed by a progressive increase in the count of red blood corpuscles.

Of the thirty-four cases treated, thirty-two responded to the treatment, but nine of these were ruled out owing to complications such as a possibility of natural remissions and the influence of some previous treatment.

In twenty-three cases the improvement could be attributed with certainty to one cause only—the administration of the liver extract.

The daily dose given was the equivalent of half a pound of fresh liver. The rise in the percentage of reticulocytes reached a maximum in 12 to 15 days, whilst the count of the red blood corpuscles rose from 750,000 at the beginning of the treatment to 5,000,000 after 34 days' treatment.

Larger doses induced a quicker response, but the "half pound" daily dose is recommended as the most satisfactory.

In addition to the work carried out by The Medical Research Council clinical experiments have been made in this country with whole liver and with liver extract by Fraser and others. These workers reported their results in the *British Medical Journal* of February 7th, 1928, summarising them as follows:—

"Nineteen patients with pernicious anemia have been treated with whole liver or a liver extract. Nine of them were in the first attack or in a relapse, and seven of these showed a prompt response to treatment, with a temporary rise in the percentage of reticulated red cells in the circulating blood, and a steady increase in the total red cells and the hemoglobin. The reason for the failure of the treatment in the other two patients is not clear.

Ten patients commenced treatment during the remission stage or received other forms of treatment in addition, so that observations on the immediate effects of the treatment were not possible. The condition of these patients at the end of varying periods of treatment (up to six months) affords confirmatory evidence of the value of this treatment."

Further, the clinical evidence furnished by Minot and Murphy in their more recent experiments with a non-protein liver extract prepared by the method of Collin

confirms the evidence produced in this country that liver extract, when properly prepared, is just as efficacious as whole liver.

Thus Liver Extract B.D.H., made in accordance with the method tested by The Medical Research Council, produces results in pernicious anemia as beneficial as those obtained with a diet of whole liver.

Method of Administration.

The advantages of Liver Extract B.D.H. over whole liver—raw or cooked—lie in its simplicity in use and in its palatability.

Liver Extract B.D.H. is prepared with hot water in an exactly similar manner to that adopted with an ordinary meat extract; that is to say, the whole of the contents of one tube—the active principle of half a pound of fresh raw liver—is emptied into a cup or other similar vessel. The cup is then filled with hot water, the mixture being stirred during the process of adding the water.

Condiments should be added to suit the individual palate, and the mixture taken as an ordinary soup or beef tea. In this way it is quite palatable.

In pointing out the advantages as to palatability and simplification of treatment in using the extract, Collin and other workers emphasise the necessity of prescribing an adequate and well-balanced diet throughout the course of the treatment.

The chief drawbacks of the liver treatment in India are: (a) that the dose amounts to half a pound of fresh liver a day; (b) that the Indian butcher often supplies cat or other liver in place of sheep's; and (c) that vegetarian patients will not take the liver if they know it to be such.

The last class, however, can usually be persuaded to take a "medicine" in place of liver extract. And in this connection the powdered extract of liver prepared by the British Drug Houses, Ltd., is of interest. This product has been approved of by the Medical Research Council of Great Britain, and is very simple in use; the contents of one tube are mixed with hot water in a cup as in making Bovril or other meat extract.

Supplies can be obtained from the Indian agents: H. S. Clark & Co., 8/10, Waterloo Street, Calcutta; and Byram Mistry, 119, Parsee Bazaar Street, Fort No. 1, Bombay.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE USE OF PNEUMOCOCCUS IMMUNOGEN COMBINED IN THE TREATMENT OF PNEUMONIA.

By G. B. BHADURI, M.B.,

Officiating Resident Assistant Surgeon, Sambhunath Pundit Hospital, Bhowanipore, Calcutta.

PNEUMOCOCCUS Immunogen Combined (Parke Davis & Co.), was first brought to our notice about the middle of December, 1928. The claims made for this preparation in the circular issued with it prompted me to give it a trial. The results to date have been as follows:—

GROUP I.

Immunogen Series.

Total treated.	Cured.	Died.	Mortality.	Remarks.
34	22	12	35 per cent.	9 died on the 1st day after admission, 2 died on the 2nd day, and 1 on the 6th day.

GROUP II.

Control Series. No Immunogen Treatment.

Total treated.	Cured.	Died.	Mortality.	Remarks.
43	18	25	58 per cent.	12 died on the 1st day, 2 on the 2nd day, 11 between the 6th and 9th days after admission.

All cases received the ordinary treatment for pneumonia, the first group, however, receiving the Immunogen in addition. It will be seen that the mortality in the Immunogen group was 35 per cent. as compared with a mortality of 58 per cent. in the control group of cases. All the cases treated were serious, as judged from their general condition, with dyspnoea and toxæmia, and all were typical clinically of true lobar pneumonia.

The Immunogen was given daily in doses of from $\frac{1}{2}$ to 2 c.c., according to the condition of the patient and the severity of the disease, until the temperature became normal and remained so for 48 hours after the injections were omitted. In desperate cases no untoward effects were noticed, even with an initial dose of 2 c.c., repeated daily until the desired result was obtained. As a rule, about 6 to 8 injections were found sufficient for a case. Clinically, after the injections of Immunogen, no marked change in the patient's condition was noticed, nor in the physical state of the affected lungs, but the termination of the cases treated with Immunogen was remarkable; even very severe cases terminated satisfactorily, and crisis—the usual mode of termination of lobar pneumonia—was not

observed in this series, thus avoiding one of the chief dangers of lobar pneumonia. The results, in brief, were so satisfactory that Immunogen is now used as a routine treatment in this hospital.

A report dealing with a larger number of cases would be interesting. A mortality of 35 per cent. is still not very satisfactory, though much better than one of 58 per cent. in the control series. Unfortunately I have not been able to obtain statistics for comparison from other hospitals. I understand that the mortality in lobar pneumonia cases in one of the largest hospitals in Calcutta is 42 per cent. The higher death rate for cases treated at the Sambhunath Pundit Hospital is largely due to the poor type of patient treated, many of our cases coming from the menial and labouring classes, who are very averse to coming into hospital for treatment, and who only come to us as a last resort when desperately ill.

My thanks are due to Lieut.-Col. A. Denham White, M.D., F.R.C.S., I.M.S., Surgeon Superintendent, Sambhunath Pundit Hospital, who very kindly authorised the trial of Immunogen, and has permitted the publication of this report.

THE TREATMENT OF VESICO-VAGINAL FISTULA BY RECTAL TRANSPLANTATION OF THE URETERS.

By J. C. FRASER,

LIEUTENANT-COLONEL, I.M.S.,

District Medical Officer, Malabar.

DURING the past ten months I have performed 24 operations for the cure of so-called "inoperable vesico-vaginal fistula." In all but two cases, the operation has been entirely successful, and of the two failures one at least should be cured by a subsequent operation.

The operation in all cases has been rectal transplantation of the ureters, the details of which, although not new, I propose to review, since repeated operations have served to bring out many little difficulties and unsuspected pitfalls which at present find no place in surgical literature.

Of all the disabilities that women are heiresses to, there is surely none more distressing than a vesico-vaginal fistula, so that anything we may do to ameliorate their unhappy lot will be of inestimable value to womankind. At its conception it is heralded in by puerperal sepsis, sloughing of the vagina and bladder-wall, severe cystitis and a high grade of toxæmia aggravated by a septic pyelitis. As the condition becomes chronic, the wretched sufferer finds herself constantly leaking urine of a strongly ammoniacal nature, so that she is not only an offence unto herself but to all her neighbours. The constant uncontrolled flow of urine sets up a chronic excoriation of the perineal and buttocks

and upper parts of the thighs, actual ulceration commonly being present, irritating and painful to a degree. The victim of the malady leaves a pool of urine, wherever she stands for a few minutes and becomes so acutely self-conscious of her cruel position that she soon retires from public life and becomes a veritable social pariah. It is a striking fact that one rarely if ever comes across an elderly woman suffering from this complaint, so that one must infer, that, worn out with suffering and ascending septic nephritis, life is mercifully cut short. There are no statistics unfortunately to prove this point, but from the septic and catarrhal condition of the bladder always associated with a fistula it is certain that the kidneys must be early infected and death hastened through nephritis.

The writer was especially attracted by the miserable condition of this class of sufferers during the four years he served as assistant to the late General Giffard at the Government Maternity Hospital, Madras, and during that time devised the vaginal operation which was published in this journal, and which he still finds largely successful for closing a fistula centrally situated. The technique of this operation consists in splitting the vesico-vaginal septum, separating the bladder from the vagina and first closing the hole in the bladder by a mattress suture passed widely from the side, and finally closing the hole in the vaginal wall. But there are a large number of cases which do not lend themselves to this *modus operandi* on account of the situation of the fistula or the total destruction of the floor of the bladder, and it is this type of case which is classed as inoperable and turned away daily from every large maternity hospital.

The treatment of fistula in the Madras Women and Children's Hospital stands where the writer left it when called to the war in 1914, his subsequent experience having been learnt in small *mofussil* hospitals, the Calicut one more especially. It was here that a patient exclaimed: "Do anything Sahib, kill me if you cannot cure me!" to which I replied, "Very well, I will transplant your ureters." The answer was an inspiration, the operation, conducted in two stages, was wholly successful and the patient left the hospital a few weeks later smiling and happy, exhibiting an extravagant gratitude, to become the nucleus of a class of similar cases which from then began to flock to the hospital.

Books on gynæcology and pathology tell us remarkably little about the morbid anatomy of fistulæ of the vagina, a knowledge of which is absolutely essential for us to decide which or other operation is the more suitable to perform. Pathologically we divide them up into vesico-vaginal and recto-vaginal, and the former we can again divide up into those involving and

those not involving the urethra. Clinically the practice has been to divide them up into operable and non-operable, although it seems better to classify them according to their position and size. Thus a vesico-vaginal fistula may be centrally situated, that is about midway between the cervix uteri and urethra and with a good margin of tissue around it separating it from the os pubis. Such a fistula I call a "*central fistula*," and it is invariably amenable to local operation. Or the fistula may be right up against the os pubis, a good sector of its circumference being composed of scar tissue rigidly adherent to bone. This I name a "*marginal fistula*," and it is almost invariably inoperable. The bulk of vesico-vaginal fistulæ are of this latter character, hence the poor results of many local operations. A third type involves the proximal end of the urethra more or less and may be called a "*vagino-urethral fistula*." This class is one calling for much judgment and may or may not be operable, thus it is always correct surgery to first attempt a local operation before attempting anything more drastic such as transplantation of the ureters. In no operation for repair of a vesico-vaginal fistula should there be any removal of tissue, such as paring the edges as many writers advocate, and this is especially to be emphasized where the urethra is involved. This structure is so short in a woman that we cannot be too conservative in preserving any portion of it. The writer well remembers a case that left the Madras Maternity Hospital to be operated on by a lady surgeon up-country, and returned without any vestige of the urethra left at all. This was a vagino-urethral fistula and so it was of the utmost importance to conserve every millimetre of the urethra. From a long experience I find that a structural repair of the urethra in a woman, where any portion has sloughed away, will always be useless, the muscle is either destroyed or loses its tone to such an extent that incontinence of urine invariably results.

Practically speaking utero-vesical fistulæ are vaginal in nature and may form a fourth class to those already mentioned, the commonest type being one which opens just inside the cervical canal and which is nearly always characterized by an entire absence of the anterior lip of the cervix, which has sloughed away from pressure at the same time as the fistula was incurred. This class of fistula is always operable locally.

Lastly we may classify fistulæ according to their size, as pin-hole, admitting a probe, admitting the tip of the forefinger, or complete loss of the floor of the bladder, the latter class, of course, being quite inoperable except by transplantation of the ureters.

The operation of transplantation must be carried out in two stages, owing to the grave risk of total suppression of urine from trauma

to the ureters. An interval of three weeks should elapse between the two operations.

The Operation.

A right or left paramedian incision is made according to which of the ureters is to be transplanted, and running parallel to the edge of rectus, extends from the umbilicus to the level of the pubes.

Skin towels are applied and the peritoneum opened. The table is then tilted to allow the intestine to gravitate to the upper end of the peritoneal cavity and, if this be not sufficient to effect the purpose, towels are used to pack off the gut.

It is quite immaterial as to which ureter should be first transplanted, some may prefer to do the right first, some the left, personally I ring the changes according to my fancy.

Search is now made for the ureter, and even to a good anatomist this structure may at times present difficulties in the finding, especially if the subject be a stout one, with much adipose tissue covering the floor of the pelvis. In a thin one it is readily seen shining white through the peritoneum or it may be felt and picked up and run between the fingers. The internal iliac may be picked up but is at once distinguished by its pulsation. Should any difficulty occur in the search, it is best to make at once for the cervix of the uterus, remembering the relationship it bears to the ureter, and the latter structure will at once be found and traced up to a favourable point for exposing it. There is nothing better for picking it up than a pair of Stiles' tissue forceps. A loop of the ureter is picked up with the aid of these and the peritoneum incised over it in its length and stripped off on either side, and as soon as buttonholed beneath the ureter, the tissue forceps are shifted so as to embrace the latter without intervening tissue. A length of ureter of about two inches is stripped free towards the cervix uteri, a catgut ligature passed through the loop, and the ureter tied as near the bladder as possible, generally about half an inch from that structure. The ureter is then divided with scissors on the proximal side of the ligature and the stump buried beneath the peritoneum with two or three stitches. It is best to divide the ureter somewhat obliquely, as if the lumen be small, it will be better exposed. In rare cases urine will be seen spurting rhythmically from the meatus, corresponding to the peristaltic waves passing down the ureter, so that it is better to place a small packing of gauze to prevent soiling of the pelvic cavity with urine.

The cut end of the ureter is then picked up and a 000 catgut suture passed through its wall into and out of the lumen at a distance of a sixth of an inch from the cut end, using a small curved needle and tying the ligature over the end, leaving a length of some nine

inches of ligature on each side of the knot. Needle and ligature ends are then wrapped up in a piece of gauze and tucked out of the way near the wound in the abdominal wall, whilst the second stage of the operation is performed. This is the opening up of the rectum to permit of the transplantation to be carried out.

Stiles' tissue forceps are again employed to seize the rectum at a suitable spot free of fat and blood-vessels and conveniently near the ureter chosen and as near the lower end of the rectum as convenient for manipulations. The outer coats are incised for about one-third of an inch down to the mucous coat which is then picked up with dissecting forceps and buttonholed with scissors curved on the flat. Any hæmorrhage at this juncture should be arrested by ligature or dangerous concealed hæmorrhage may take place into the bowel.

The needle, threaded on one end of the ligatures holding the ureter, is now taken and passed through the opening in the bowel and made to pierce its coats one inch from the opening at a point down the bowel. The ligature is drawn through and its end clamped with a pair of Spencer Wells' forceps. The needle is threaded on the second ligature and again passed into the bowel and brought out at a point near the first. By drawing on the two ligatures, the ureter can now be drawn into the rectum for about an inch and secured or anchored to the inner wall by tying the two ligatures without. The opening in the bowel is then closed with a single ligature which also pierces the outer coats of the ureter to further secure it from slipping out should the first ligatures cut through early. The last stage of the operation is the complete burying of the exposed portion of ureter, which should be done in a similar way to Witzel's method for burying the tube in gastrostomy. A continuous 30-day 000 catgut suture should be used for this, and the last one or two stitches should secure the rectum to the wall of the pelvis to prevent its weight dragging too heavily on the ureter. All that now remains is to make a careful toilet and sew up the abdominal wall in layers.

Special points in the operation which may call for attention:—

(1) The ureters may be of unequal size and, if very small, may be very difficult to find. In one of my cases the right ureter was at least four times the calibre of the left and, as I operated on the left first, I had considerable difficulty in determining the structure, in fact it was not until I incised the organ that I was convinced that so thin a structure could be the ureter. On operating later on the right side, I found a ureter resembling a loop of small intestine, so great was its calibre.

(2) There may be only a single ureter; a ureter much larger than normal should at once give rise to this suspicion. A mistake here will mean a second useless operation. In a case of a single kidney with the very real danger of suppression of urine, one might feel justified in not going on with the operation. In but few cases is the ureter seen to emit tiny spouts of urine, proving that there is at least a temporary stoppage in the peristalsis of the ureters or an actual suppression of urine from the particular kidney in the majority of cases.

In the few cases mentioned I have felt justified in going on with the second operation of transplanting the other ureter at once, to save the patient from a second abdominal section.

(3) Hæmorrhage from the rectum.

This is a very real danger and happened in one of my cases, some two pints or more escaping from the anus later on in the night with the formation of a pelvic hæmatoma. Since this accident, which did not however end fatally, I have used meticulous care in arresting even the smallest bleeding points in the rectal wound, and have had no further recurrence of the accident.

(4) Retention of urine in the rectum.

Many patients are tolerant from the first of urine in the rectum, so that if not passed some hours after the operation, it is advisable to pass a tube and allow it to escape in a bedpan. Distention of the rectum with urine is to be especially remembered at the second operation, or on opening the rectum, the wound may be soiled by a mixture of urine and fæces. The appearance of the rectum is very characteristic in such cases, its wall appearing translucent and œdematous. The remedy is to wash out the rectum immediately before the operation and to drain it afterwards.

(5) Accompanying disease of the pelvic organs.

This unfortunately is only too common and is to be expected in this country, especially after pelvic sepsis resulting from a morbid confinement. The presence of pelvic tumours is not a contra-indication of the operation but *it is best to postpone operation on them till later*, firstly because it is infinitely easier to transplant a ureter in a pelvis free from adhesions, secondly because it may lead to dangers like hæmorrhage. In the case mentioned above, there was a small broad ligament cyst present which I removed before transplanting the ureter, and I am inclined to think that this was mainly responsible for the after-trouble.

(6) Interval between the two operations.

In my first cases I allowed a full three weeks to elapse, sometimes longer; now I am guided entirely by the secretion or not of urine into the rectum. In nearly every case, there is a slight diarrhœa present on the

following day and the motions are found to contain urine. Keep an eye on your bed-ticket, and if you find the bowels are opened three or more times in the day, as soon as the first wound has healed and consolidated, you can go ahead with the second transplantation without any fear of untoward results—thus the two operations may be carried out in a single fortnight, a useful point where beds are a consideration.

(7) Presence of a recto-vaginal fistula.

A small recto-vaginal fistula is apt to be overlooked through the vesico-vaginal one obscuring its presence. Such actually happened in one of my cases and to my great chagrin, I discovered urine still escaping from the vagina after having transplanted both ureters. It was only with the greatest difficulty that the rectal fistula was afterwards closed. If any doubt should arise, it is always as well to distend the rectum with a solution of methylene blue and watch for its escape per vaginam. Should a fistula be discovered, it must be closed before undertaking the transplantation of the ureters.

(8) Post-operative fever.

In a fairly large percentage of our cases it was found that the temperature rose on the third day and fell by lysis during the next three or five days. No pain was complained of, nor was there anything to account for the fever. It was obviously not reactionary from the operation, as it was delayed. I am now inclined to think that it is due to a passing or transient ascending pyelitis or ureteritis and, as the fever is of but short duration, do not attach much importance to it. A rise of temperature on the third day need not give rise to a causeless alarm such as the possibility of a leakage from the rectum or cut end of the ureter. This accident must be very rare as it has never occurred in my series of cases.

Before concluding it is essential to discuss the merits and demerits of the operation, for the just criticism which will be levelled at my head will be that the thrusting of the ureters into a septic focus, such as the rectum must be, is only to invite an ascending pyelitis and surgical kidney. I am quite prepared to admit the charge but at the same time it must be pointed out that the bladder, exposed as it is to sepsis when a large fistula is present, is as great a danger as the one arising from ureteral transplantation, and, as a matter of fact, we know that such patients suffer constantly from pyelitis which ultimately destroys them. Granted then that we do not add to the patients' longevity of life, we at least alleviate their declining years by freeing them from an intolerable discomfort. Situated as I have been, without the facilities for research offered in a large institution, I have been unable to carry out any blood-urea tests, which I think should be carried out, in order to determine if any absorption of urine occurs

from the rectum. A surprising tolerance shows itself in most patients on the part of the rectum, which appears to retain large amounts of urine without any desire being expressed by the patient to go to stool. This is so marked that we now advise patients to empty their rectum regularly every eight hours lest they should absorb their own urine. Free diuresis is another factor observed and may be due to the diuretic action of urea absorbed from the rectum. No uræmic symptoms have been observed so far, indeed the mentality of our patients has been wonderfully improved and brightened.

Of all cases operated upon, the total mortality has been nil, the failures have been two, but a third case left the hospital after the first ureter was transplanted, refusing to have a second abdominal operation performed. As a consequence of this, we make it a point to tell the patient that the urine is escaping from two holes and that we can only close one hole at a time, hence two abdominal operations will be required. The simplest-minded patient can understand logic of this sort so that it is unlikely that any more will abscond.

MALIGNANT ANÆMIA OF THE TROPICS.

By F. P. MACKIE, K.N.S.,
BREVET-COLONEL, I.M.S.,

Director, The Haffkine Institute, Bombay.

A SEVERE and often fatal anæmia was recognised as occurring in Bombay as long ago as 1906, and as the result of the investigation of a series of cases a paper bearing the above title was read at a local medical society in 1907. The paper was not published but on going over my old note books I find all the material laid out, and in view of further researches which have been and still are being undertaken into the anæmias of Bombay I think it of more than merely historical interest to make a summary of these observations, the more so because the present state of our knowledge is not very greatly in advance of that which prevailed over twenty years ago.

Within the last few years some information on the subject of the anæmia of sprue has been collected, particularly as a result of work which has emanated from this Institute. (1) A considerable volume of work on the anæmias of pregnancy has been collected here also by Dr. Margaret Balfour and her assistants in an enquiry financed by the Indian Research Fund Association, which has in the last few months received further impetus from the engagement of a special research worker from England.

The alarming prevalence of a dangerous and generally fatal anæmia amongst pregnant women led to the belief that this was a disease peculiar to or predominant amongst women, whilst the

similar clinical condition in sprue patients was attributed to the effects of this disease. The object I have in resuscitating these ancient records is to show that this fatal type of anæmia has long been prevalent in Bombay and that it is not confined to pregnant women nor to sprue patients, but is found amongst males and non-pregnant women and is in fact to be met with in all classes of the community, and is found in most other parts of India when special enquiries have been made to elicit its presence.

These facts suggest that pregnancy and sprue are not specific factors, but that some other cause is at work and that the disease is precipitated by conditions of undue physiological stress.

My original cases were all collected from the wards of the J. J. Hospital or the European General Hospital and were all in males.

When these observations were made I was an assistant at this laboratory (which was then known as "The Plague Research Laboratory") and had always been specially interested in blood diseases and had paid particular attention to pernicious anæmia in British hospitals and to malarial and other secondary anæmias in this country. Hunter's classical researches on the former disease had only recently appeared and I was thoroughly familiar with the literature of the subject, so that it is interesting to see that in almost every case which I studied I remarked that the clinical and hæmatological picture presented by this "malignant anæmia" did not closely resemble pernicious anæmia as described by Addison and Hunter. With much wider experience of tropical anæmias my opinion is just the same to-day, and I believe that this disease as we see it here will be found to be of the nature of an aplastic anæmia, often megalocytic in type, and that it can be distinguished both clinically and hæmatologically from Addison's anæmia.

I will give now a brief account of the clinical and laboratory notes on the cases which I studied in 1906-1907.

There were nine cases of which all were males, the youngest being 14 years of age. Five were Mahomedans, one Hindu, two Parsis and one an Anglo-Indian. Six out of the nine died, and three left hospital of their own accord without marked improvement. Two cases of pernicious anæmia, both contracted in England, which relapsed here and four cases of severe post-malarial anæmia were also studied side by side with the above nine cases, but are excluded from the present series. Neither of these six "control" cases died while under observation.

All the nine cases of "malignant anæmia" were in poverty stricken persons and some of these had recently been subjected to conditions of great hardship and privation. Three of these were Mahomedans who had just returned from the pilgrimage to Mecca.

Several had a history of irregular fever from time to time in the past, but no evidence of recent malaria was found in any case nor were malarial parasites found in any of the blood examinations made extending over the period of investigation.

The usual complaint on admission was weakness, emaciation, dyspnoea and oedema of the lower extremities. Several cases had bruising of cellular tissues or slight hæmorrhages from the nose or mouth, whilst one died from repeated hæmatemesis. Scurvy was not diagnosed in any case. An evening rise of temperature (to about 100°F.) was noted in several cases. The spleen was readily palpable in two cases whilst in another there was considerable enlargement of both spleen and liver with ascites, so that Banti's disease was at first diagnosed.

Blood crises were noticed in several cases, if a sudden drop in the blood count and the appearance of distorted and immature cells can be so described.

The mucous membranes were very pale and in several cases ivory white. In only two cases were there signs of marked oral sepsis. The tongue was pale and flabby but not irritable as in sprue. Abdominal distension was noted in two cases and recurrent pale diarrhoea in the same two cases, but intestinal disturbance was not a feature of the majority except that terminal diarrhoea was noted in most of the fatal cases.

The skin was pale and the surface rough and dirty and in some cases showed irregular pigmentation. The lemon yellow tinge of Addison's anæmia was not noted nor was the blood serum icteric.

The heart was invariably fast and the sounds feeble or embryonic whilst hæmic murmurs were almost invariable at one or more of the orifices.

No affections of the respiratory tract were noted. No involvement of the nervous system was met with and signs of disease in the spinal tracts were sought for without success. The ordinary urinary and fæcal examinations were done but nothing abnormal was found. A few ancylostoma eggs were found in one case but that factor could be excluded as a cause of the anæmia in this and in the other cases.

Changes in the blood.—The reduction of red blood cells is profound, more so than in the majority of cases of Addison's anæmia and in several cases it reached a limit incompatible with life.

In the successive examinations of these nine cases the lowest blood count was 417,675 per c.mm. Other low counts were 429,000; 583,000; 558,000; 650,000; 716,000; and 983,000. The rest were between 1 and 2 million, whilst the highest was 2,016,000 per cm.

The leucocytes were reduced to a less extent. Most cases showed counts between 2,000—4,000 per c.mm. With the exception of one which had a leucocytosis of 14,093, none were above normal limits.

The relative proportion of the leucocytes was almost invariably altered in the same direction, namely an increase of the small mononuclear cells at the expense of the neutrophilic leucocytes.

The proportion of the large mononuclears was never increased and in only one case was there a pronounced eosinophilia.

The hæmoglobin figures were very low and varied from 10 per cent. to 36 per cent. The colour index was over unity in eight examinations and less than unity in seven.*

The blood counts were done from the finger blood, checked in most cases by that obtained by vein puncture, for in the extreme cases sufficient blood could not be obtained from the finger without bandaging the whole hand.

The blood was extremely thin and watery and sometimes scarcely showed red in the pipettes, whilst the films on slides were thin and greasy and scarcely visible to the naked eye. Auto-agglutination of erythrocytes was a common phenomenon and the blood in a watch glass separated out into a granular debris with clear untinged plasma. There was no naked eye evidence of hæmolysis or altered pigment. When examined fresh the red cells were of variable sizes, chiefly large cells and microcytes and poikilocytes with few cells of normal size. Micro-meter measurements supported this view. In stained preparations the red cells were mutilated or fragmented and showed considerable poikilocytosis, chiefly of the microcytes. Chromatophilic changes were not at all frequent, and normoblasts or megaloblasts were very rarely seen.

This and the other signs of blood regeneration were conspicuous by their absence and this was in contrast with the cases of Addison's anæmia which were studied side by side with the cases of malignant anæmia. The clinical course was that of progressive anæmia without remission leading to death. The general picture, both hæmatological and clinical, suggested an aplastic anæmia and it is much to be regretted that no autopsy was permitted in any of the six cases and the condition of the bone marrow could not be observed.

Other examinations.—Spleen punctures were made in most cases and liver punctures in a few—the puncture fluids were subjected to prolonged study at room temperature, at ice box temperatures, by aerobic and anærobic cultivation and by dark ground illumination. Blood was injected into guinea-pigs and monkeys but no effect was observed. There was an increase in coagulation rate as estimated by Wright's method. Cross hæmolytic experiments were made with normal serum and normal corpuscles and it is interesting to note that the blood serum of the patients was not in the least degree hæmolytic to normal cells nor was there undue fragility of the patients' red cells in the presence of normal serum. The phenomenon of iso-hæmophagy (which at that time had just been described) was looked for but not found.

CONCLUSIONS.

(1) Evidence accumulated in 1906-07 shows that there was prevalent in Bombay a severe type

* The hæmoglobin was measured by Gower's method with tinted gelatin and checked by Fleischl's apparatus. Too much stress cannot be placed on these figures as both these standards are known to fade in the tropics.

of anaemia which was recognised as being distinguishable from pernicious anaemia and from the secondary anaemia associated with malaria, ankylostomiasis and similar tropical conditions.

(2) The clinical and hæmatological features as then described suggest that the anaemia was of aplastic type.

(3) This type of anaemia has been recognised as of considerable frequency in Bombay since that time, and is probably similar or identical with that described as occurring with particular frequency in connection with sprue and with pregnancy.

(4) The fact that this "malignant anaemia" is met with in males and in non-pregnant women and apart for sprue indicates that it is a disease *sui generis* and is liable to develop in those suffering from debilitating or diseased conditions or as a result of undue physiological stress.

(5) The resuscitation of these old notes is of more than historical interest in that modern observations support those made at that time that there was then and is now a type of profound and often fatal anaemia prevalent in Bombay and in many parts of India which differs both from Addison's and the "secondary" anaemias and which, however originating, is probably associated in its later stages with an aplastic condition of the bone marrow.

A REVIEW OF MALARIA DURING 1928 IN A MINOR HILL STATION IN THE PUNJAB.*

By G. M. IRVINE,

CAPTAIN, I.M.S.,

Officer Commanding, Indian Military Hospital,
Bakloh.

THERE are certain aspects of interest in the malaria problem as presented in Bakloh. The

* Published by permission of the Director of Medical Services, India.

station has considerable natural advantages in its favour, being a hill station of an average altitude of 4,500 feet, and situated on a well-drained ridge without any permanent or semi-permanent local feature which could be regarded as a potential danger from the malarial standpoint. Notwithstanding this, a study of the figures of past years reveals the fact that it has a high incidence of malaria.

A reference to Table I shows that the admission rate per 1,000 for malaria of all troops in the station for the past year was 113. This is a high figure, taking into consideration its natural advantages. It compares unfavourably with the corresponding figure for the whole Indian Army for 1926—the last year for which statistics are available—when it was 115 per 1,000. This figure is rendered still more remarkable when it is considered that Dalhousie, which is about 5 miles away as the crow flies and 1,000–1,500 feet higher, with local and climatic conditions somewhat similar, is absolutely immune.

As might be expected, it has always been considered that the great majority, if not all, the malaria in the station was imported. All the evidence goes to point to such a conclusion. There are, however, certain gaps in the information available and it was with a view to filling in these gaps and arriving, if possible, at a more definite conclusion regarding the source of the disease that the present investigation was undertaken. In the review certain points of interest yielded by the series from the clinical standpoint—questions of diagnosis, etc.—are also included.

In dealing with cases an endeavour was made to base the diagnosis of malaria on microscopic findings. It is found with increasing experience that, in a frank case of the disease, in which the diagnosis can be made with confidence on clinical grounds, parasites will almost invariably be found; provided quinine be withheld; and that, in those cases in which systematic examinations fail to

find them, there is at least a certain amount of doubt from the clinical standpoint. In the present series, of a total of 108 cases 98 were diagnosed microscopically and 10 clinically. The latter figure is regarded as too high. It should not be necessary to diagnose as many as 9 per cent. of all cases as "clinical malaria." Six of these 10 were cases of remittent or intermittent fever in which the usual clinical and bacteriological investigations—blood culture for typhoid, etc.—yielded no results, but which, though not clear cut cases of malaria, approximated to it more than anything else. In retrospect it is considered with these that a freer resort to the old fashioned diagnosis of "pyrexia of unknown origin" might have been made with advantage. I exclude 4 cases, 2 of which had had quinine before they were seen, and 2 among children who were taken away from hospital before the necessary investigations could be carried out.

In this context—to digress somewhat from the subject in hand—a plea might be made for a more sceptical attitude regarding "clinical malaria." In the tropics this tends to be what "influenza" is in the United Kingdom, namely a rubbish heap, to which are relegated those febrile conditions which fail to fall satisfactorily into the known categories. The diagnosis of "P.U.O." is regarded as a confession of failure and has of recent years fallen into disuse. Doubtful febrile conditions are accordingly diagnosed as "clinical malaria," "clinical typhoid," etc., depending rather on the leanings of the observer at the time. This attitude is based on the assumption that all tropical fevers have been satisfactorily classified, a position which few would be so rash as to maintain. Were the defects in our knowledge in this respect frankly recognized and those febrile conditions which fail to fall satisfactorily into a definite category diagnosed as "P.U.O.," valuable material would be afforded which by its correlation might be used for their further classification which is at present admittedly incomplete.

The object of having the diagnosis on microscopic findings in all cases and eliminating the "clinical case," is considerably furthered by the routine use of the thick drop method of staining blood films. This method is less popular and receives less prominence in textbooks than the thin film method, though it has many apparent advantages for routine clinical work and yields—certainly in my hands—a higher percentage of possible slides.

Its advantages may be briefly summarized as follows:—

(a) Parasites, in the ordinary positive case, are usually found on the first or second field examined, thus effecting a great saving of time.

(b) By the concentration of the parasites in a drop of blood in a comparatively small area, these will frequently be found in cases of scanty infection when they would be missed altogether in a thin film. That such is the case will be realized from the fact that in cases of heavy infection as

many as 90 parasites have been counted in a single field, using the ordinary $\frac{1}{2}$ inch objective.

(c) Three or four minutes' systematic search is sufficient to call a slide negative, as against the 12 to 15 required with a thin film.

(d) Its preparation is simple and demands no skill on the part of semi-trained subordinates who have to take the films, as does the thin film, the successful preparation of which involves a certain amount of technique which is often beyond them.

The criticism directed against the method is that it is impossible to determine the type of parasite seen. This difficulty has been exaggerated, and with increasing familiarity in its use it has been found possible in the majority of cases to differentiate between *P. vivax* and *P. falciparum*, which, as there is no record of quartan infection occurring, is the practical point to be decided. Where accurate work is essential, the thin film is superior, but for routine clinical work any uncertainty as to the type of parasites present is more than counterbalanced by the greater certainty of finding them. That this is very definitely the case is shown by the fact that in the 98 cases diagnosed microscopically, parasites were found in thick films on the first examination in 94 cases: in 4 cases they were found in the second film and in no case in the third.

One last point of interest from the clinical aspect provided by the series was an illustration of the truth of the aphorism that in pyrexial conditions the finding of the malaria parasite does not necessarily mean that it is the causative agent. Of three cases of pyrexia during the year from whose blood *B. typhosus* was subsequently isolated, malaria parasites were found in the blood of two on admission. They were accordingly diagnosed as malaria, but when the pyrexia did not yield to quinine therapy, investigations with a view to a diagnosis of typhoid were made, with the result as stated. In such cases pitfalls will only be avoided by adhering to the routine of sending blood for culture in all cases in which the pyrexia does not yield by the 6th or 7th day to quinine. In this respect, as regards the difficulty caused by the "quinine-resistant" case, a reference to current literature on the subject will show that there is a growing tendency to regard quinine resistance as a great myth—or at any rate extremely rare.

In those apparently "quinine-resistant" cases observed by the writer the explanation has always been either that the quinine was not absorbed, as evidenced by failure to find it in the urine, or that the malaria was complicated by some other condition, more commonly the former.

It is a common experience to find the parasite in the graver pyrexias, pneumonia, surgical conditions, etc., where it is obviously not the causative agent. In such cases its appearance in the peripheral circulation is merely an expression of the lowered powers of resistance of the patient, which allows the previously latent parasite to proliferate at the expense of its host.

Following the above comments suggested by a review of the disease from the clinical standpoint, it now remains to determine to what extent it is contracted in the station, and if imported from what source. The most obvious lines of enquiry were to determine

(a) the extent to which the disease was prevalent among the indigenous population, and

(b) the presence or otherwise of vectors among the anopheline population.

There is abundant evidence that the disease is uncommon among the local inhabitants. There is a remarkable absence of the usual seasonal *bokhar* in the bazaars and among local servants, such cases as there are being usually found not to be permanent residents. Accurate figures are not available, as there is no cantonment or other public hospital for the civilian community, but the foregoing facts were ascertained sufficiently definitely from the cases who come for extern treatment at the military hospital, where it is recorded, and also from the subordinate medical personnel who do the private practice in the bazaar.

That the local community is remarkably free from the disease is borne out by the result of a spleen index carried out by Captain J. G. Joyce, I.M.S., in November 1927. Of 199 children and juveniles from the bazaar who had been born and spent all their lives in Bakloh, only one was found with an enlarged spleen. In this case other causes of splenic tumour were not excluded. The above figure points strongly to the conclusion that of the total volume of malaria in the station that amongst the indigenous population constitutes a very small fraction, if any.

As, however, there is no public hospital where accurate observation of malaria among the civil community is possible, which would yield reliable figures, attention was directed to those two sections of the indigenous population amongst whom accurate observation was possible, namely the families of serving soldiers and what are known as "recruit boys." There are about 480 troops' families in the station comprising in all 1,000—1,200 women and children and for these a scheme for the provision of hospital treatment has been inaugurated during the past year. Although the women are almost all from Nepal and accompany their husbands on leave out of the station, from time to time, a large proportion of the young children have lived in the station from birth. The incidence of the disease among them therefore will be an indication of the prevalence of indigenous malaria.

For the past nine months blood films of all children with febrile conditions were taken, three examinations being made if necessary. In all cases in which parasites were found the child's history was investigated with a view to determining the possibility of infection having taken place outside the station at any time in its recent history. Of all such cases 2 were found with parasites in their blood who had lived in Bakloh since birth and had therefore contracted the infection there.

As regards the recruit boys, these are chiefly sons of serving soldiers who had been born in the station and had never subsequently been away from it. About 30 of these "boys" are enrolled in the units at the age of 10 to 12 years and come under medical supervision in the same way as the rank and file. During the year, though a careful watch was kept for malaria amongst these 30 "boys," no case was observed.

The cases among the children prove that malaria can be contracted in the station. The fact, however, that there were only two such cases and none amongst recruit boys bears out the previous conclusions from observations among the bazaar population and from the spleen index that its volume is extremely small. The children in question constitute a large proportion of the total strength of the families, running into several hundreds. They are in the most intimate contact with their parents, who, as will be shown, are frequently infected and constitute reservoirs of the disease. No steps are taken for their protection such as the provision of mosquito nets, etc., and, as childhood is the period of greatest susceptibility to malaria, one would expect them to show a high rate of incidence, if opportunities for infection existed to any great extent. The reverse, however, is the case. The disease was noted to be rare among young children generally, with the exception of a small "rush" which took place among families which had just returned from leave in Nepal in October, in whom the infection was obviously contracted either there or on the journey.

As regards the anopheline vector in the locality, the only previous record was that of Col. Frost, I.M.S., in 1916 to 1918. The investigation was not a systematic one and was based on the identification of occasional specimens—about 20 in all—captured casually in the 2 years. The varieties identified according to the record were *A. theobaldi*, *A. turkhudi*, *A. willmori*, *A. maculipalpis*, *A. lindesayi* and *A. gigas*. The only other information on the subject is by Major G. Covell, I.M.S. (*Indian Medical Research Memoir* No. 5, February, 1927), who gives the following varieties:—*A. willmori*, *A. turkhudi*, *A. stephensi*, *A. lindesayi*, and *A. gigas*.

The period and extent of the investigation are not known.

With a view to compiling as accurate and comprehensive information as possible regarding the anopheline population, steps were taken during the past year to collect specimens which were sent to the Central Malaria Bureau, Kasauli, at intervals of a few days to a week throughout the entire breeding season from April to September. Although there are considerable discrepancies between the findings of this investigation and the previous record, taking into consideration the size of the series, the fact that care was taken to secure specimens equally from all parts of the station—which was checked by a "spot map"—and that identification was carried out by expert malariologists, it is probable that it represents an

accurate classification of the anopheles in the station.

The following were the varieties identified among the 250 specimens sent for identification during the season:—

(a) *A. willmori*. This is the predominant type and was found from the middle of May to the end of September. About three-quarters of the total specimens were of this variety.

(b) *A. lindesaii*. This was the next in order of frequency and was found in April, May, and June.

(c) *A. maculipalpis*. Five specimens only were found, about the middle of June.

(d) *A. gigas*. A single specimen was found in April.

Breeding places were found to be chiefly in the small kutchha nullahs which carry off water from taps and standpipes in bazaars, lines, etc. The spot map showed all parts of the station equally affected.

Of the above varieties *A. lindesaii* and *A. gigas* are considered to be guiltless of any part in the transmission of malaria. *A. maculipalpis* is a recognised vector. As regards *A. willmori* the situation is by no means so clear. Gill (1920) has succeeded in experimentally infecting this variety with *P. vivax* at an altitude of 7,000 feet and himself contracted infection from a bite of a laboratory bred specimen. Nevertheless, he observed that, in the vicinity of Srinagar where *A. willmori* was found in large numbers, the human carrier also being present, indigenous malaria was extremely rare—a state of affairs exactly analogous to that found in Bakloh. In spite therefore of the experimental evidence outlined, the most recent view of Indian investigators is that further investigation is necessary before it can be definitely incriminated.

As far as Bakloh is concerned, the evidence is against it being an effective vector. As will be shown, there is a large reservoir of infection, which is constantly being replenished, and yet there is very little indigenous malaria, facts which would be difficult of explanation in the presence of a vector found in large numbers throughout the entire breeding season, as was *A. willmori*. On the other hand the explanation that *A. maculipalpis*, 5 specimens only of which were found in the series, and which is an effective "carrier," is the sole guilty agent, would appear to be more in keeping with the facts.

Having decided that the bulk of the malaria in the station is imported, there arises the problem of the probable source. It will be seen that there is ample opportunity for its contraction elsewhere and a solution may be arrived at by an analysis of the figures to determine how far the periods of maximum incidence correspond with the arrival of men from outside, and the classes chiefly affected.

Of the two Gurkha battalions permanently stationed here, each is absent on the Frontier two years in six. It is probable that a proportion of the imported malaria is contracted during this period, as they frequently serve in malarious

stations. It has not, however, been possible to observe the effect of a return of troops from the Frontier on the incidence of the disease, as this has not occurred during the year under review.

In addition to the absence of a battalion on the Frontier, another opportunity for infection outside the station is given by the departure of the greater part of the unit, or units, each winter to a large station on the plains for training, where they remain from October to February. It might be possible that a proportion of infection is contracted then. A reference to Table I will show that there is a rise in the figures for March, the month following the return. The increase, however, is negligible and obviously has little or no effect on the total incidence.

The only other possible source is arrivals from Nepal, i.e., leave parties and recruits, which, as they arrive at, or about, the same time, may be considered together. In the year about 200 men are absent on furlough in Nepal for seven months and normally return at the end of October. The recruits arrive in five or six batches a little later—towards the end of November and the beginning of December. An analysis of the figures shows that the maximum incidence in the year coincides with these arrivals, and that practically all cases occurring subsequent to this are from amongst these men.

From the beginning of the year up to 19th October, there were in all 29 cases of malaria among troops, or 35 per cent. of the whole yearly total. Between that date and 31st December, there were 53 or 65 per cent. It will be observed that this sudden rise in the malaria graph takes place at a time when, under normal epidemiological conditions, the seasonal prevalence of the disease is subsiding. That it was so subsiding is shown by the fact that in October, up to the 19th, there were only 4 cases, whereas in the last 12 days there were 17, all with one exception from furlough men who had returned a few days before.

It was not possible to observe the total incidence among them, as the majority proceeded with the unit on manoeuvres at the end of the month. That it must necessarily have been extremely high is shown by the fact that there were in all 26 cases from amongst them in the last 10 weeks of the year, including the above 16 cases, and 10 others occurring among the few men of the party who remained behind in the station. It has since been ascertained that a large proportion of this leave party who proceeded on manoeuvres went down with malaria within a few weeks.

The result of the routine medical inspection of these men carried out on their arrival further emphasizes the high percentage of malarial infection incurred among them either in their homes in Nepal, or on the journey. The main body—about 150 strong—arrived on 23rd October, and were inspected on the 24th. Amongst them, 9 were found with temperatures above normal. Of these 9 cases parasites were found in the blood of 7 in films taken on the spot.

As regards the recruits arriving at the end of November, and beginning of December, the findings were parallel: 108 in all arrived from Nepal and among them there were 19 cases before the end of the year, occurring from a few days to three weeks after arrival. This shows an incidence during this six weeks of 176 per 1,000, without including those cases which were admitted to hospital for malaria at their recruiting depot at Gorakhpore.

The probable effect of arrivals from various sources on the incidence of malaria has been indicated. Table II is an analysis of the figures for the whole year among troops, showing the proportion in which the various classes were affected. For this purpose troops are divided into (1) those permanently resident in the station, i.e., those who had been three weeks or more in the station previous to the development of an attack of malaria; (2) recent arrivals from the Frontier; (3) furlough party returning late in October; (4) recruits arriving in November and December.

TABLE II.

	Cases during year.		
(1) Permanent residents..	35	43	per cent.
(2) Arrivals from the Frontier.	2	2	"
(3) Furlough party ..	26	32	"
(4) Recruits ..	19	23	"
TOTAL ..	82		

As the mean temperature had dropped below 60°F. and mosquitoes were no longer in evidence by the end of October, it is presumed that in all cases included in (2), (3) and (4) infection had been contracted before arrival. According to these figures, therefore, 57 per cent. of the total malaria in the station is imported, and 43 per cent. is apparently indigenous. There is, however, no doubt that a large proportion of this 43 per cent., which cannot be determined, represents recrudescences of infection contracted elsewhere, in Nepal, on the Frontier, etc. Table I shows, for instance, that of the total of 108 cases in the year under review 96 were relapses and only 12 fresh attacks. It is probable, therefore, that the malaria actually contracted in Bakloh is much less than that suggested by the latter figure.

As regards the source of infection in the 45 cases among furlough men, the men's villages suggests itself as the most obvious solution. This is undoubtedly a very prolific source in the Indian Army generally, and the most strenuous efforts made to reduce the incidence by the prosecution of elaborate anti-malarial measures in a station are frequently in great measure stultified by the arrival of heavily infected leave parties. In the case of the Gurkhas serving in this station, however, this is not likely to be the case. The lower-lying parts of Nepal, such as Katmandu and its vicinity, are known to be malarious, but the men do not come from such areas. Their homes lie chiefly on the higher ranges at altitudes of 5,000

to 6,000 feet where conditions are less favourable to the propagation of malaria. In most cases one failed to elicit any history of fever in their villages, whereas many gave a history of fever on the way back.

It is much more likely that infection occurs on the journey. This will be readily understood when it is considered that this lies through the Terai—a belt of territory lying astride the Nepalese border, partly in Nepal and partly in the United Provinces. It consists largely of irrigated land, swamp, and jungle, and is regarded as one of the most malarious areas in the entire sub-continent. According to an account of a malarial survey of part of this region as given in the *Indian Medical Year* (May 1928), 60 per cent. of all deaths occurring among the population are due to malaria. Only 5 per cent. of the villages in the region surveyed were graded as healthy, while 62 per cent. were graded as hyperendemic.

In view of this, and the fact that the journey through the area, lasting three days to a week, is ordinarily performed on foot, the possibilities of infection occurring will be manifest. Furlough parties and recruits are traversing the region at the time of the maximum seasonal prevalence of malaria. They break their journey at the various villages and local centres on the way, where they spend the night in close proximity to rich reservoirs of the disease without protection against infected mosquitoes. In addition to this, according to information supplied by an experienced Gurkha officer, who is familiar with the conditions, the men are frequently at a low physical ebb, as the result of the rigours of a trying journey which takes up to three weeks and is performed chiefly on foot. They have often to sleep in the open, exposed to chilly nights and heavy dews. Suitable food is scarce and difficult to obtain and, where obtainable, they have often not sufficient funds to keep themselves properly supplied. Under such conditions their powers of resistance are lowered and they are rendered more susceptible to infection with the resulting high percentage of malarial attacks among them.

CONCLUSIONS.

1. Bakloh, considering its position as a hill station and its natural advantages, shows a high rate of incidence of malaria.
2. The majority of this—probably over 70 per cent.—is imported.
3. The chief source of infection is men arriving from Nepal, who contract the infection when passing through the Terai.
4. As far as the evidence in Bakloh is concerned, this is against *A. willmori* being an effective vector.
5. *A. maculipalpis* is responsible for the majority—if not all—of the indigenous malaria in the station.

My acknowledgments are due to Major R. A. Mansell, O.B.E., R.A.M.C., for his advice and encouragement and to Captain H. W. Mulligan, I.M.S., of the Malarial Survey of India, for his

very kind reply to my query regarding *A. willmori* and the present position regarding the evidence implicating it as a "carrier."

OBSERVATIONS ON THE POTENCY OF INDIAN DIGITALIS.

By R. N. CHOPRA, M.A., M.D. (Cantab.),
LIEUTENANT-COLONEL, I.M.S.,

and

PREMANKUR DE, B.Sc., M.B. (Cal.), M.R.C.P. (Edin.).

Department of Pharmacology,
Calcutta School of Tropical Medicine and Hygiene,
Indigenous Drug Series No. 1.

In a previous paper (1926) we pointed out that *Digitalis purpurea*, although not indigenous to India, was imported into the country and cultivated not only as a garden plant but also for medicinal purposes. There are three main situations in which it is grown on large enough scale for commercial purposes.

1. The Nilgiri Hills where the plant was introduced many years ago. It grows there mostly now from self-sown seeds but a certain amount is regularly cultivated. It is largely supplied by the cinchona plantations there to the Government Medical Store Depot at Madras and also to the manufacturing pharmaceutical chemists in that Presidency.

2. In Mungpo near Darjeeling where a plantation was started many years ago in connection with the cinchona plantation. The site selected was at an altitude of about 6,000 feet above the sea-level and a great deal of care was exercised at one time to cultivate the plant on scientific lines. This has, however, been given up and when the senior author visited the place last year he found that regular cultivation was practically stopped and the leaves were being collected from self-sown seeds and were collected irrespective of age. A few small plantations have been recently started by private individuals who are supplying leaf to manufacturing firms in Calcutta and other places.

The leaves here are picked from April to June, are spread in thin layers and allowed to wither for 36 hours, being turned over occasionally to prevent fermentation. As it is not possible to dry the leaf completely in the air, the drying is completed in ovens at a temperature of 150°F. This procedure is necessitated by the heavy rainfall in this part of the Himalayas at that particular time of the year when the digitalis leaf is picked.

3. In Kashmere during the last few years the Forest Department of the State have taken a great deal of interest in cultivating digitalis on a commercial scale. They have started a number of plantations, one of which the senior author had the opportunity of visiting with the Conservator of Forests, Utilisation Division. The plant was being systematically cultivated, the seedlings were reared in nurseries, and blocks of ground were cleared of jungle and dug up to put in the

seedlings. It has been realised by the authorities that the leaves collected during the first and second year of growth have the highest glucoside content, therefore these only are collected. After this the plantation is dug up and fresh seedlings replanted. The leaf here is entirely air dried and special methods were being tried by the officer in charge to dry it in such a way so as to lose as little of the active glucosides as possible. Once the leaf is properly dried no special precaution is taken to store it in the plantations. It is generally kept in dark sheds or rooms by simply heaping it on the floor and covering with a mat. The atmospheric temperature in these places is not high and the leaves do not appear to lose their active principles by fermentive processes. The leaf is tightly packed in wooden boxes before it is despatched to the manufacturing pharmaceutical chemists.

The plantations in Kashmere are still in their infancy and cannot supply all the orders which are sent to the Forest Department. It is hoped, however, that in a few years they will be able to grow sufficient leaf to meet all the demand.

Potency of Indian Digitalis Leaf.

During the last year or so we have assayed a large number of tinctures, mostly prepared from the Indian grown leaf, sent to us by some of the big manufacturing firms of Calcutta. The method adopted for assay is a modification of Hatcher and Brody's cat method which was introduced by the authors several years ago and which was fully described in a paper published in the *Indian Journal of Medical Research* (1926a). The modification consists in studying with a stethoscope, at regular and frequent intervals, the heart of the animal used for assay and carefully noting down any changes in the character, frequency and rhythm of the heart beat. We have frequently checked the results obtained by actual clinical trials of the tinctures in patients and found that the potency of the specimen as judged by this method of assay practically runs parallel with the therapeutic effectiveness of the specimen in human beings. The method briefly stated is as follows:—

Cats weighing from 1.6 to 2.5 kilos are selected and are starved for 12 hours before use. The anæsthetic employed is 0.17 gm. of chloretone per kilogramme body-weight injected intraperitoneally dissolved in a few c.c. of alcohol. In this way the animal is deeply under anæsthesia in about ten minutes. It is important to have the animal properly under anæsthesia and under no circumstances should a second anæsthetic be given to the same animal while the assay is being done; this vitiates the results. If the animal is not properly under anæsthesia with chloretone alone, which is very unusual, it is desirable to

discard it. The tincture is diluted with normal saline and is filtered through a layer of cotton-wool placed at the bottom of the injecting burette. This prevents passage of emboli into the vein. It is then injected into the femoral vein, the rate of flow being adjusted in such a way as to complete the assay in from 45 minutes to 60 minutes. Throughout the assay the heart of the animal is carefully auscultated every few minutes; the beats are counted and any change in the characters of the sounds produced by the drug is recorded. Special attention is paid to the following points:—

(1) The amount of tincture required per kilogramme to produce a well marked slowing of the heart.

(2) The degree of slowing and any alteration in the character of the sounds.

(3) The total duration of slowing, or digitalis action.

(4) The time required for completion of the assay and the total amount of tincture per kilogramme body-weight to produce that effect.

All the four points are taken into consideration in conjunction with one another in judging the strength of the preparation.

The following table gives an analysis of 60 specimens of tinctures assayed in our laboratory by this method, during the last year or so:—

TABLE I.

Source from which the leaf was obtained.	ACTIVE.		INACTIVE.		Average slowing of heart rate (including active and inactive).	Remarks.
	Total.	Percentage.	Total	Percentage.		
Kashmere..	11	91.7	1	7.3	57.1	
Nilgiris ..	9	90	1	10	37.2	
Mungpo (Darjeeling).	6	50	6	50	36.3	
Unidentified	6	50	6	50	40.2	Mostly Indian grown leaf.
Foreign ..	8	57.1	6	42.9	27.1	

A perusal of Table I shows that tincture made from the Kashmere leaf produced the maximum slowing of the heart; then follow the unidentified group; the Nilgiri and the Mungpo leaf came next, and last of all the tinctures prepared from imported or foreign leaf. The unidentified group was composed chiefly of tinctures made from Indian grown leaf. It will further be observed that Kashmere leaf gave the largest number of active preparations, i.e., 1 out of 12 tinctures examined only being inactive; next come the Nilgiri leaf, 1 out of 10 inactive; then the foreign leaf, 6 out of 14 inactive; and last of all the Mungpo and the unidentified leaf, 6 out of 12 inactive in each case. Probably the

reason why Mungpo digitalis leaf does not such good results as the others is that the of drying it in an oven at a temperature of 150 F. is defective. There is no doubt that glucosides are not split up at a dry temperature of 150°F., but it is very difficult to regulate the temperature so as not to exceed that limit; frequently the temperature runs considerably higher in these ovens. This no doubt produces deterioration of the glucosides and consequent loss of potency of the leaf.

Storage is also a very important factor (Chopra, Bose and De, 1925; Chopra and De, 1926b). The leaf after drying is generally heaped up on the floor of a darkened room in the plantation, but here the temperature as a rule is not high and fermentative processes are not so easily set up, especially if the leaf is properly dried. In the plains, however, the temperature is high in the hot weather and in places like Calcutta it is very humid. Even if the drying of the leaf is not defective, absorption of moisture from the air mostly saturated with moisture produces rapid deterioration of the glucosides unless special care is taken in storage. Light is another important factor. Macht has shown that not only sunlight but even moonlight may produce deterioration of the glucosides, and unless this is rigidly excluded the leaf rapidly loses its potency.

As regards the period of storage, careful inquiries regarding the leaf used in preparation of tinctures examined by us shows that under ordinary conditions when the leaf is kept in tin-lined boxes in a moderately dark place, it shows progressive signs of deterioration and as a rule become therapeutically inactive in two to three months in a climate like that of Calcutta. If kept in air-tight tins, with rigid exclusion of light and in a cool place it lasts considerably longer and it is estimated may be kept for six to nine months or even a year without materially losing its potency. Formerly the imported leaves were stored in bags heaped up in shelves, but this method has now been discarded by most of the big firms.

Another point of interest brought out by this investigation is that 20 out of 60 tinctures submitted to us for biological assay were *absolutely inactive* and had to be condemned as being unfit for therapeutic use. All these tinctures were prepared by reputable firms who employ a well trained and experienced staff. They also obtained the best quality of the leaf and took all possible precautions as regards storage in a cool, dry and dark place in tin-lined boxes. If these precautions are not taken the percentage of inactive tinctures will undoubtedly be considerably higher. The danger of using preparations which have not been standardised may thus be readily comprehended by the physician who, if not careful, may be using

an absolutely inert tincture with perhaps disastrous results.

We wish to express our gratitude to the Bengal Chemical and Pharmaceutical Works Ltd., Calcutta, Messrs. Smith Stanistreet & Co. of Calcutta and the Union Drug Company of Calcutta for the trouble they have taken in giving us information about the origin and storage of leaf from which the tinctures sent for assay were prepared.

Summary and Conclusions.

(1) A very good quality of digitalis leaf can be cultivated in suitable places in India. The chief places where it is grown at present are the Nilgiri Hills, Mungpo near Darjeeling (Southern Himalayas) and Kashmere (Northern Himalayas).

(2) The potency of the Indian grown leaf compares favourably with that of the imported leaf.

(3) In this series Kashmere leaf gave the maximum slowing of the mammalian heart, next came an unidentified group composed chiefly of Indian grown digitalis; then the Nilgiri and Mungpo leaf, and last of all the imported leaf.

(4) Proper storage is an important factor. The leaf rapidly deteriorates in a hot and moist climate such as that of Calcutta, if stored in ordinary tin-lined boxes, not fully protected from light. If stored in air-tight boxes in a cool and dry place, the deterioration is slow and the leaf may remain active for 6 to 9 months.

(5) One-third of the total specimens of tinctures prepared from all kinds of leaf for the market which were sent to us for assay were found to be absolutely inactive and had to be condemned and discarded. As these were prepared by reliable firms under most favourable conditions, the danger of using unstandardised preparations can be readily understood.

THE INTENSIVE TREATMENT OF KALA-AZAR BY NEOSTIBOSAN; PART II.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.,
Kala-azar Research Worker, Calcutta School of Tropical
Medicine and Hygiene,

and
M. N. MULLICK, M.B. (Cal.),
House Physician, Carmichael Hospital for Tropical
Diseases, Calcutta.

In August last year the writers contributed a paper on the intensive treatment of kala-azar by neostibosan. Some thirty cases were

reported; the progress of the patients during their stay in hospital and their condition at the time of discharge were described. In one of the concluding paragraphs we stated "This communication is by way of being of a preliminary note as it is not possible to say definitely yet whether these patients are completely cured or not. The writers can only say that in their opinion all the previously untreated cases are behaving as if they were now completely cured and they will be extremely surprised if of the whole series more than, say, two relapse. The patients will be followed up and a report on their subsequent history issued later."

It may be remembered that the course of treatment consisted of 8 injections given on 8 consecutive days, the total amount of the drug given to an adult being 2.3 grammes. The subsequent history of the thirty patients is as follows:—

Not traced	3 (Nos. 30, 26, 22).*
Died within probation period (6 months), of disease other than kala-azar.	1 (No. 23).
Remained well for at least 6 months subsequent to discharge, i.e., cured.	21.
Kept under observation for 4 months after last injection, at the end of which period serum showed complete "serological cure"; cured.	2.
Definite clinical relapse.	2 (Nos. 18 and 20).
Apparent relapse, but fever possibly malaria.	1 (No. 15).

30

The first 4 must be excluded from our calculation as the fate of the first three is unknown, and the fourth died of an intercurrent disease, enteric, within the six months' period. Of the remaining 26, 3, or 11.5 per cent., must be classed as relapses, and 23, or 88.5 per cent., were completely cured.

Of the 26 patients, 3 had previously had a full course of treatment and had relapsed; of these 3 patients one relapsed again. Therefore, of the 23 patients who had previously not had a full course of treatment, only 2, or 8.7 per cent., relapsed.

This concentrated course has now been adopted as the routine treatment in the Carmichael Hospital for Tropical Diseases.

* These numbers correspond to the case numbers in the original paper.

Calcutta. At least 100 more patients have been given this course and on only two occasions have we had to modify the course on account of the condition of the patient.

As this course of treatment has now passed the experimental stage, and will possibly be adopted more widely, it will perhaps not be out of place if, again, we draw attention to the fact that in half the cases there was practically no clinical improvement at the conclusion of the course of injections, but that the marked improvement commenced from this date. In the 23 cured cases the average length of duration of fever from the commencement of treatment was nearly 10 days and in only 10 cases was the temperature normal before treatment was finished, although it might be mentioned that in the three cases now classed as relapsed the fall of temperature was delayed and occurred on the 15th, 17th, and 20th days, respectively.

The advantages of this course of treatment will be much more appreciated in hospital than in dispensary or private practice, especially in view of the fact that we are not at present prepared to claim that it has any advantage, except in the matter of time, over the more extended course. For the hospital patient there are obvious advantages in this short course. Beds are valuable, and most hospital superintendents, in order to prevent their hospitals becoming choked with patients, place a limit in the number of kala-azar patients that may be in hospital at one time. Nevertheless, there is no reason why it should not be given to out-patients if they can be persuaded to attend so frequently; we have given daily injections to two laboratory assistants on our staff whilst they have been carrying on their ordinary duties.

With eight injections we have obtained a high percentage cure rate, but by increasing the course to 10 injections it seems probable that an even higher rate might be obtained (incidentally, this is a point which is at present under investigation). As there is no conceivable disadvantage—except in the matter of the extra expenditure—in giving an additional two injections, we feel compelled to suggest that, where expense is not a matter of primary importance and until the cure-rate curve has been satisfactorily worked out, 10 injections should be adopted as the routine course.

INTRAMUSCULAR INJECTIONS.

In the series reported there is only one case in which the drug was given by intramuscular injection. This patient was cured. We have adopted this method of treatment in about 20 cases altogether now and the results have been entirely satisfactory. Doses of 0.3 gramme of neostibosan in 25 per cent. solution in distilled water injected into the gluteal or deltoid muscles, preferably the former, are

well tolerated; in few instances was there any complaint of local pain and in only one—out of about 200 injections—was there definite local inflammation with abscess formation.

LEPROSY IN MANIPUR STATE.

By G. G. CROZIER,
Manipur State, Assam.

THE treatment of leprosy was begun in Manipur in 1918 with the co-operation of Sir Leonard Rogers and the Inspector-General of Civil Hospitals of Assam. The writer was told that at that time the Census Report indicated the presence of 160 lepers in the State. Since then 173 cases have been admitted to the Mission Leper Colony and the State has started a hospital and dispensary work for lepers and has admitted 198 cases, and other cases are known in both regions served by these two institutions. The writer had several years' experience with the use of leprolin in the Garo Hills, but has been following Sir Leonard Rogers and Dr. Muir since starting the work in Manipur. Of those admitted to the Mission Leper Colony, 118 were males and 55 females. They are grouped by ages as follows:—

Prenatal	..	1
Age 1—9	..	1
10—19	..	33, mostly early cases.
20—29	..	41, mostly early cases.
30—39	..	56
40—49	..	31, mostly advanced cases.
50—59	..	8
60—69	..	2
Total	..	173

Of the 21 dying of intercurrent diseases, 6 were of the 30 to 39 group and 9 in the 40 to 49 group.

The prenatal case had a trophic ulcer $\frac{1}{2}$ by $\frac{3}{4}$ inch in size on the plantar surface of the heel at birth that did not heal with ordinary methods, but healed promptly with local applications of chaulmoogra oil. At 6 months she had a three inch circular discoloured anæsthetic patch on the left scapular region that entirely cleared up with three months of semi-weekly hypodermic injections of chaulmoogra oil and creosote. She is still living (5 years old) with her father and father's mother—both lepers—in the Colony and seems perfectly well; her mother, a leper, died there from ascites of unknown cause. Her maternal grandmother was also a leper.

The Mission Leper Colony serves the hill tribes; it has no dispensary cases, for there are none living near. The State hospital and dispensary serves the Hindus, Mohammedans and others of the plains. From the beginning the State officers have co-operated well, and as soon as they saw the results of treatment they began a systematic search of their respective areas for all cases of leprosy, requiring them to come for treatment or to live

a mile away from their villages; and this practice has become an order of the State Darbar. The sub-divisional officer of the hills of the north-east wrote a year ago that he thought he had sent all the cases there were in his area. The sub-divisional officer of the south-west said recently that he thought there were but few left in his area. There are some cases left in the hills of the north-west but they are being cleared out as rapidly as possible. Careful survey has not yet been made in the extreme south-east and in the central north. In the villages on the plains the difficulty is greater and approximate knowledge of the incidence of the disease is not available.

Of the 40 cases discharged as probably cured, only those discharged in the absence of the writer have returned for further treatment. It is the custom at the Mission Lepers Colony to treat all cases till they seem clinically to be cured, then disinfect them as thoroughly as possible, segregate them from other cases and continue the treatment for two months longer. They are then discharged with certificates in duplicate, one kept by the patient and the other sent to his government headquarters for registration, where they are required to report for inspection bi-monthly. The writer and his medical assistant inspected during the latter half of January this year seventeen of these cases as shown below, aside from the prenatal case:—

months before we had intended to discharge him; he was in the same region as the first of the series.

It will further be noticed that these have been discharged an average of about 25 months only, a bit too short to be sure they will not relapse; four of them were just over three years.

The first case has been just over nine years without treatment, after eleven months and 24 days treatment. He had several large anæsthetic patches; all seemed to clear up under treatment. It appears that treatment for him should have been continued longer. He had mainly the sodium hydriocarpate intravenously.*

The moral effect on all but the first has been very helpful, for they seem very happy at present.

Manipur is such a concentrated area that it is believed the hill section of the State can be nearly cleared of the disease in a few years more. The early cases will have become "cured" and returned to their homes, and the "burnt-out" cases will probably be retained in the Colony as an asylum. The State provides money for the food for all cases, blankets, and salary of local overseer; other agencies provide the buildings, medicines, and medical service.

* This case was discharged in the absence of the writer, believing himself not to be cured, and returned later for further treatment.

17	Lathuila ..	f	B1	25-7-26	30- 4-27	28-1-29	do.

It will be noticed that these are practically all early cases.

It will be observed that (omitting the first case) these were under treatment an average of almost exactly one year.

No. 12 of this series was a mild case of his class.

We have not had the opportunity of inspecting other discharged cases. We saw one case badly relapsed who had left a few

ON THE RATIONALE OF TREATMENT OF CARCINOMA OF THE CERVIX UTERI.

By SUBODH MITRA, M.D. (Berlin), M.B. (Cal.),
F.R.C.S. (Edin.),

Superintendent, Chittaranjan Seva-Sadan, Calcutta.

In order to have a clear idea of the treatment of cases of carcinoma of the cervix

uteri, the pathological anatomy of the part should be considered to a certain extent.

Pathological Anatomy:

There are too many classifications of carcinoma uteri, making the subject complex and too complicated. For all practical purposes we shall stick to Schottländer and Kermauner's classification which is as follows:—

Macroscopically, the condition is divided into:—

- Exophytic, and
- Endophytic growths.

An *exophytic* growth is one which has got a tendency to grow outwards inside the vagina. It takes the proliferative or cauliflower-like form. Symptoms appear earlier, and the cancer cells are more radio-sensitive.

An *endophytic* growth eats in to the cervix, sometimes keeping the outward form of the cervix intact, at other times forming a crater-like ulceration. The growth extends commonly into the parametrial tissues, and the lymphatic glands are frequently affected. Symptoms appear rather late, and the prognosis of this type of growth is worse on account of early infiltration of the parametrial tissues.

Histologically Schottländer and Kermauner have divided carcinoma of the cervix uteri into:—

Primary solid carcinoma; 94.6 per cent.

Primary glandular carcinoma.

Secondary solid carcinoma (from glandular carcinoma).

Solid carcinoma arises from pre-existing squamous epithelium metamorphosed as such by metaplastic changes of cylindrical epithelium. Solid carcinoma may also arise from the surface epithelium of the portio uteri, but it is rare (about 2 per cent.).

Parametria and Lymphatic glands:—

Carcinoma of the portio uteri spreads in all directions and especially towards the parametria. Clinically, the parametria feel indurated in these cases, but in some cases they do not. Wertheim has shown that in 22.5 per cent. of cases the parametria remain quite soft in spite of their being infiltrated by carcinoma cells, while in 14 per cent. of cases, the parametria are quite indurated and yet they are free from cancer cells. This induration is due to round-celled infiltration. This shows that in the management of carcinoma of the portio uteri cases it is not only the local growth which is to be treated, but the parametrial tissue as well should be looked upon with suspicion in each case, no matter whether it is infiltrated or not, and be dealt with accordingly. Similarly the pelvic lymphatic glands—chiefly the iliac and sacral group—should be taken into consideration, because they show cancer metastases in about 25 per cent. of cases as evidenced by Wertheim from his 500 cases.

Historical Review of Treatment:—

Formerly, cases not being early and properly diagnosed, almost all of them were treated too late, and declared hopeless. Canterisation was the main line of treatment. Freund of Germany was the pioneer to take the rational step of treating cases by abdominal section (1878). About six months later, Czerny of Germany began to do vaginal hysterectomy in similar cases, having a primary mortality of 32 per cent. in his 81 cases. Freund did abdominal section in 95 cases, of which 65 died and the remaining 30 cases did not escape recurrence. The primary mortality being very high, abdominal operation for carcinoma cervix was given up for the next twenty years, until the technique was modified by Bardenheuer by introducing vaginal drainage: and this simple modification reduced the mortality to 33 per cent. Since then, surgical procedures have been improved more or less continuously until 1895, when Riess, Rumpf and Clark simultaneously began to do extensive operations by removing not only the uterus but also the parametrial tissues and the regional pelvic glands. They had this initiative from the surgical principles followed in treating cancer of the breast. But it was left to Wertheim to establish the technique of the modern radical operation. After a laborious study of the method of growth of uterine cancer, and a careful observation and consideration of results following simple hysterectomy, he has shown that a surgical cure can only be possible after all the extensions and ramifications of the growth have been removed.

Schauta recommends para-vaginal operation by making deep lateral incisions in the vagina to obtain wide exposure of the vaginal vault, cervix and parametria. This operation is advocated particularly in fat patients.

Other measures taken for dealing with carcinoma uteri are cautery treatment, acetone treatment, and the treatment by innumerable drugs, e.g., arsenic, mercury, copper, cacodylate of sodium, cholesterine, orthocoumarate of soda, and recently specially prepared lead solution. Lead is still in the experimental stage, while the others have not stood the test of time.

Radiotherapy in Carcinoma of the Cervix Uteri.

During the last two decades the radium treatment for carcinoma has come into the field, and is slowly and steadily gaining ground, both from the palliative and curative standpoints. More recently radium treatment has been supplemented by deep roentgentherapy. Radium acts by destroying cancer-cells and at the same time by stimulating the growth of fibrous tissue, so that after a complete course of treatment one gets a soft scar in place of carcinomatous growth.

B- and Y-rays of radium have an effective value up to 7 cm. distance; if the growth extends more deeply than that area, radium rays cannot possibly have much effect unless radium tubes and needles are buried inside the tumour. American workers and the Brussels Radium Institute do bury needles, but the Radium Institutes of Paris and Stockholm do not advocate it. We follow the latter schools because introduction of needles may disseminate cancer cells, and the injured normal tissue might be unfavourably affected by radium, and thirdly owing to the devitalised condition of the parts there is more chance of sepsis.

Intra-abdominal application of radium was recommended by Daels of Ghent, by putting the radium alongside the iliac glands. It is not advocated nowadays.

As radium can act efficiently only locally within an area of 7 cm. and intra-tumoral application of radium not being very much recommended, the advanced cases can be treated better by combining deep roentgen-therapy with radium treatment. According to Seitz and Wintz the lethal roentgen dose for carcinoma is 90 to 100 per cent. of S.D.D. The uterus with its appendages and parametria usually lie about 10 cm. deep from the skin surfaces. In order to obtain 110 per cent. of T.D. in 10 cm. deeper tissues, roentgen exposures have to be from all sides, and the intensity of the rays being accumulated at the seat of tumour, we get the desired dose provided the x-ray machine works with really high voltage tension. We have estimated the deep percentage dose in the Seva-Sadan with the ionto-quantimeter, and have got 30 per cent. of E.D. under 10 cm. water-phantom when working with 180 K.V., 4 M.A., 0.5 mm. copper 1 mm. aluminium filters, 30 cm. F.S.D., and a portal of entry 10 cm. by 15 cm. When roentgen exposures are given from anterior, posterior and the two lateral surfaces of the pelvis, we get on an average about 110 per cent. E.D. at the seat of disease.

Operation or Radiation in Carcinoma-Cervix Uteri.

This question can only be solved by carefully scanning the results in both methods after at least five years' observation. In the recent International Congress held in Stockholm in July, 1928, Heyman brought forward exhaustive statistical results, thus giving us opportunities of judging the cases more critically than we could do before.

Operation Statistics.—3,659 cases were collected. They had radical operations done by surgeons of different lands having an average cure (after 5 years) of 35.6 per cent, the primary mortality being 17.2 per cent. From table I, we find that Wertheim did 450 cases with a primary mortality of 19.6 per cent. and

Zweifel ..	251	120	47.8
Franz (Berlin) ..	296	133	44.9
(Jena) ..	87	33	37.9
V. Frankque ..	36	14	38.9
Bumm ..	179	77	43.0
Davis ..	20	8	40.0
Busse (Kroenig) ..	58	19	32.2

a cure rate of 41.3 per cent. Victor Bonny did 192 operations with a primary mortality of 16.2 per cent. and a cure rate of 40.6 per cent. Schauta did 445 cases, having a primary mortality of 8.9 per cent. and a cure rate of 34.6 per cent. Bumm did 179 cases with a primary mortality of 12.3 per cent. and a cure rate of 43.0 per cent. Kroenig did 73 cases with a primary mortality of 39.7 per cent. and a cure rate of 5.5 per cent. Franz did 296 cases with a primary mortality of 14.2 per cent. and a cure rate of 44.9 per cent, and Zweifel did 251 cases, with a primary mortality of 7.6 per cent. and a cure rate of 47.8 per cent. From the above facts we find that successful operation results vary from 5.5 per cent. to 47.8 per cent. The result depends not only upon the efficiency of the surgeon, but also upon the selection of cases. A low percentage of primary mortality, and high percentage of cures indicate that only very early cases were operated.

Radiation Statistics.—Heyman has also collected the results of radio therapy in 3,512 unselected cases (i.e., operable, borderline and mostly inoperable cases) having a cure of 16.3 per cent (Table II). From his own 500 unselected cases, he shows a primary mortality of 1.6 per cent. and a cure rate of 12.4 per cent. after 5 years' observation. Regaud of Paris had 201 cases with a cure rate of 12.4 per cent.; Doederlein treated 1,068 with a cure rate of 13.3 per cent. and Wintz of Erlangen had 415 with a cure rate of 17.1 per cent. The results of radiation therapy

have also been noted in 960 selected cases, i.e., operable and borderline cases, having a cure rate of 34.9 per cent. Heyman had 144 cases with a cure of 44.4 per cent.; Doederlein had a cure rate of 30.8 per cent. in his 357 cases, and Menge had a cure rate of 55.6 per cent. out of his 63 cases. No statistical results in radiation therapy are forthcoming from British surgeons.

The number of operable and borderline cases treated with radiation therapy is still too small for comparison with the number dealt with by operation, still it is obvious from the facts and figures given that radiation therapy (Table III) stands on the same

level with operative therapy, and all the more gains ground from having practically no primary mortality.

The results obtained by radical operation in England and on the Continent can never be obtained in India, because the constitution of average Indian women is too frail to bear the shock of a severe radical operation. The percentage of primary mortality would be enormously high. And if the question of operation is to be considered in surgery for cancer of the uterus, Wertheim's radical operation is the only operation of choice. Simple removal of the uterus either per vaginam or abdominally can never be a satisfactory or rational way of treatment. The idea of prophylactic radiation therapy after vaginal or abdominal hysterectomy is not quite ideal. Prof. Rigaud says: "Preliminary hysterectomy is a mistake, because it scatters malignant cells. Under the circumstances, it is to be admitted that of all the forms of treatment in carcinoma of the cervix uteri, radiation therapy deserves the first place, and is the treatment of choice in India."

A YEAR'S RECORD OF KATA-THERMOMETER READINGS AT RANGOON.

By G. G. JOLLY, C.I.E.,

LIEUTENANT-COLONEL, I.M.S.,

Director of Public Health, Burma,
and

V. W. FENN, L.M.F. (Bengal),

Assistant Bacteriologist, The Harcourt Butler Institute
of Public Health, Rangoon.

It is now generally recognised that the mere observation of the temperature of the air in a room by means of an ordinary dry bulb thermometer is no index of comfort and gives no measure of the rate of loss of body heat in it. The thermometer measures the degree, not the quantity of heat, and gives no measure of radiation, or of humidity, of drying power or cooling power, exerted on the skin. To measure the cooling power the kata-thermometer was first introduced by Leonard Hill. Since air velocities can also be calculated rapidly and accurately with it, it is of very great value for testing atmospheric conditions in schools, factories, etc. The wet kata-thermometer is of particular value in warm atmospheres where skin perspiration is pronounced, as in the tropics and in textile mills and mines.

The first systematic kata-thermometer readings to be undertaken in Burma were begun on the 4th January 1927, and thence every week for a whole year readings were recorded. It is hoped that these will furnish useful preliminary data from which to formulate a relative comfort standard under the conditions existing in the country. Considering that for each type of work there are

definite atmospheric conditions for optimum comfort, and that those for one type cannot be held as good enough for any other, it was decided that readings should first be taken in the Public Health Institute at Rangoon, and later in various other localities for comparison. By dividing the year into the three main

	Dry bulb F°.	Wet Bulb F°.	Dry Kata.	Wet Kata.
Hot Weather .	84.38	71.16	2.51	11.59
Rains .	85.53	83.76	3.14	10.61
Cool Season .	82.66	71.16	4.80	16.37

seasons which obtain in Burma, i.e., the hot weather, the rains and the cool season, the mean of each season is obtained.

From the above it will be seen that the nearest approach to Leonard Hill's comfort standard for sedentary work (i.e., dry kata not below 6 and wet kata not below 18) is not secured on the average even in the cold weather. Actually there were only four days throughout the whole year in which this standard was attained.

The weekly readings were taken in the routine Bacteriological Laboratory of the Harcourt Butler Institute of Public Health, Rangoon, which is a room measuring 32 feet by 26 feet by 14 feet having its main exposure facing north and also an external wall facing east. The room has five windows and two doors. The readings were taken with doors and windows open to natural ventilation, the ventilating area being 1,808 square feet.

The readings are given below:—

Kata-Thermometer Readings Taken Weekly during the Calendar Year 1927, in the Bacteriological Laboratory of the Harcourt Butler Institute of Public Health, Rangoon.

Longitude East 96° 9' 20".

Latitude North 16° 47' 26".

Height above sea-level 152 feet.

Date and hour.	Dry Therm. F°.	Wet Therm. F°.	Dry Kata.	Wet Kata.	REMARKS.

KALA-AZAR IN BIJNOR.

By M. UMAR, P.M.S.,

Medical Officer, Bijnor, U. P.

THERE was a time, when I was a student of medicine, when one was taught that kala-azar was endemic in Assam and certain portions of Bengal only. But investigation has shown that it is very common in other parts of India, e.g., a case was proved in a boy living in Aminabad (Lucknow) who had never left Lucknow.

As far as is known to me, no case of kala-azar had ever been diagnosed in the district of Bijnor, and I can confidently say that I am the first person to diagnose the disease in this district.

I give below a list of cases recently seen by me.

Case No. I.—K., a Hindu, came to hospital on April 18th, 1928, very thin and weak, and with a spleen very much enlarged. His blood was taken on April 19th, 1928, and serum was examined on April 20th, 1928. The formol-gel and urea-stibamine tests were positive, but he died before any treatment could be undertaken.

Case No. II.—M. S., admitted May 3rd, 1928. He was a lad of 18 years; spleen enlarged down to the umbilicus. He was reduced almost to a skeleton. I induced his mother, with much difficulty, to bring him to hospital. It is a very peculiar thing that in India those who require admission to hospital never agree to be admitted, but those who do not require in-patient treatment invariably complain if they are not admitted.

This boy had a continued fever which never went up to more than 102°F. Four injections of urea-stibamine brought the spleen to half its former size, and a further four injections cured him. The formol-gel and urea-stibamine tests were both typically positive. He left the hospital cured—a good healthy-looking, fit lad.

Case No. III.—N., Hindu female, admitted on July 28th, 1928. Her spleen was very large. The formol-gel and urea-stibamine tests were positive. She disappeared from hospital without anyone's knowledge.

Case No. IV.—N., aged 36. Muslim female (Shia). Admitted on August 14th, 1928. The spleen was hard and enlarged down to the umbilicus. There was a well-marked leucopænia. The formol-gel and urea-stibamine tests were positive. She was treated with the old tartar emetic treatment. After four injections improvement was felt, but she left the hospital without undergoing further treatment.

Case No. V.—N., aged 10 years, Hindu male child, had fever with rigor. Spleen 3 finger-breadths below the costal margin. The formol-gel and urea-stibamine tests were positive. He also was treated with tartar emetic. He left hospital cured.

Case No. VI.—B., aged 15, Hindu male, admitted September 9th, 1928. Spleen down to umbilicus. Fever with rigor present. Both tests were positive, but after one injection he disappeared.

Case No. VII.—K., a Muslim of 65 years, with a very big spleen extending below the umbilicus. He was also positive, but after a few injections of Neostibosan he left the hospital, as the harvest was ripe and was being destroyed by birds.

Case No. VIII.—M., aged 45, Hindu, admitted with enlargement of the spleen. Both tests positive. His spleen disappeared. In this case also Neostibosan was used.

All these people were residents of Bijnor District. In none of these cases was there any enlargement of the liver. All had leucopænia.

From the above results I would like to suggest that medical officers in other districts

of the United Provinces might enquire into suspicious cases and publish their results. I am convinced that this disease, far from being rare in these provinces, is one which is extremely common. I have been so struck with the number of cases which respond to the test and to the treatment, that I now, in every case of chronic enlarged spleen, test for kala-azar. The cases which are generally positive are those which might be mistaken for chronic malaria, chronic dysentery, and certain cases of abdominal dropsy.

A great handicap is the cost of treatment. With the present grants for drugs being as small as they usually are, it is impossible to treat even a fraction of the cases which come under one's care with urea-stibamine or Neostibosan; and until District Boards are more generous in this matter, or the hospitals are provincialised, it will only be possible to undertake the old treatment with tartar emetic, except in the case of those who are able to pay for their treatment.

(*Note.*—An exact knowledge of the geographical limits of a disease is a matter of considerable importance; in the case of kala-azar it is particularly so, as the method by which the disease is transmitted from man to man is as yet unknown and any additional information regarding its distribution is of the greatest value to the research worker. From the time it was first recognised as a disease entity it was realised that kala-azar was widespread in Bengal, Bihar and Assam, and that there was a focus of the disease in Madras city. For many years it has been recognised in the United Provinces as far west as Lucknow. Major-General Megaw used to say that the cases he saw in Lucknow, where he worked for many years, always originated in places east of the town. During the last fifteen years the endemic area in Assam has extended, and more recently new foci of infection have been discovered in southern India. We do not know when Dr. Umar ceased to be "a student of medicine," but we cannot agree with the suggestion that recently the kala-azar distribution map of India has undergone any serious revision, although isolated, and somewhat doubtful, cases have been reported from time to time from places well outside the recognised endemic areas. This does not mean that our knowledge is by any means complete; the research workers on the subject cannot wander haphazard about India looking for cases of kala-azar, but are dependent on enthusiasts like Dr. Umar for giving indications.)

Dr. Umar's paper was received some months ago and there has been a considerable amount of correspondence between us on the subject.

We are not by any means satisfied that any of the cases reported above are cases of kala-azar. In no instance was the parasite demonstrated. The diagnosis was dependent on clinical observation and on the serum tests. It is quite natural that those who have had no experience of a definitely positive "aldehyde reaction" should be misled by a result in which there is complete solidification and a marked degree of clouding of the serum. Recently, Dr. Umar came across another similar case; he sent us a spleen puncture smear and the serum for the aldehyde test. He had done this test and considered it definitely positive. We found no parasites in the spleen smear and the aldehyde test was very definitely *not* positive; complete solidification occurred in a few minutes and the serum became cloudy, but after 24 hours light could be still seen through it, and it bore no resemblance to the solid *completely opaque* result which is obtained in an advanced case of kala-azar.

A point raised by Dr. Umar in the correspondence between us was "In all my cases why was the disease cured by urea-stibamine, Neostibosan and antimony tartrate, if all these were not cases of kala-azar?" This

is certainly a point, as in our experience in Bengal this condition of splenic enlargement described by Dr. Umar, when unassociated with the presence of leishmania, does not usually yield to antimony treatment. However, from Dr. Umar's notes, which are necessarily very concise, one does not gather that *all* the patients were cured; in fact at the widest stretch the word could only be applied to Cases II, V and VIII.

Whereas for the diagnosis and treatment of the individual a clinical diagnosis is often sufficient, although in the case of kala-azar we consider that this should be supported by at least one of the very simple serum tests; if the case is to be used to upset our previously conceived ideas regarding the limits of distribution of the disease, it is essential that the parasite should be demonstrated, and we would also suggest that the specimen be submitted to an expert for identification.

We hope that neither he nor any of our readers will consider that criticism is levelled against Dr. Umar. On the contrary, we welcome his contribution, and, if he will excuse our patronage, we commend his enthusiasm. We hope that the publication of this note may encourage others to look for cases of kala-azar originating in areas where the disease has not previously been reported.—(Editor, I. M. G.)

THE CARNIVOROUS HABITS OF INDIAN "BLOOD-WORMS."

By S. MUKERJI, M.Sc.,

*Entomologist, Ancillary Kala-azar Research,
Schaal of Tropical Medicine, Calcutta.*

At Cossipore, Calcutta, on the 29th August 1928, in a shallow exposed pot full of rain water, I secured a large number of mature larvæ of *Chironomus* (sp.) with the intention of breeding them out. This pot was peculiar in that it contained only *Chironomus* larvæ, whereas other exposed pots in the same neighbourhood also contained mosquito larvæ in varying numbers. A few of the *Chironomus* larvæ were kept in watch-glasses without any food supply except what they could obtain from the scum at the bottom. It was noticed that when the scum at the bottom of the glass was disturbed the larvæ emerged from the recesses which they had made in the scum, and swam rapidly with the characteristic double-loop movement.

No further particular attention was paid to the larvæ until it was suddenly noticed that their number had become considerably reduced. As the watch glass was securely covered, the only explanation for their reduction in numbers was that they were carnivorous. This belief was further strengthened by the fact that when the burrows were closely examined they were found to be composed of fragments of larval organs.* Only such larvæ as could construct tunnels in the scum escaped injury or death. The larva protrudes its head from the tunnel, and in this process its "pseudo-leg" helps the head in its eversion. When frightened or teased it retracts into its tunnel, its tentacular terminal

segments aiding to some extent in the retraction.

The larvæ pupated on the 15th September inside narrow tubular burrows, and the adults emerged a day or two after pupation.

My reason for recording these observations are that perhaps by suitable technique *Chironomus* larvæ might conveniently be employed in keeping down the number of mosquito larvæ in a particular area: their carnivorous habits might be made use of to some extent in the biological control of mosquito breeding. One would further appeal for publication of any similar observations.

SPECIAL ARTICLE.

PROCEEDINGS OF A CONFERENCE HELD AT BIRNAGAR (BENGAL) ON SUNDAY, THE 24TH FEBRUARY, 1929, AT 2-30 P.M., TO DISCUSS THE PROBLEM OF MALARIA CONTROL AT BIRNAGAR.*

By K. BOSE,

Honorary Secretary.

PRESENT.

1. Sir Malcolm Watson, M.D., LL.D., *President.*
2. Dr. C. A. Bentley, C.I.E., M.B., D.P.H., D.T.M. & H., Director of Public Health, Bengal.
3. Major H. Suhrawardy, O.B.E., M.D., F.R.C.S.I., D.P.H., Chief Medical Officer, E. B. Railway.
4. Major H. Lockwood Stevens, Organising Secretary, Ross Institute.
5. Captain B. S. Chalam, L.R.C.P., L.R.F.P.S., Malariologist, E. B. Railway.
6. Dr. S. N. Sur, M.B., D.P.H., D.T.M., Assistant Director of Public Health, Malaria Research.
7. Dr. P. C. Dutt, M.B., Ch.B., F.R.C.S., L.R.C.P., M.R.C.S., District Medical Officer, Kanchrapara, E. B. Railway.
8. Dr. G. Bose, D.Sc., M.B., Chief Medical Adviser, Palli Mandali.
9. Mr. N. Banerji, M.A., B.L., Chairman, Birnagar Municipality.
10. Rai A. C. Mitra Bahadur, B.E., President, Palli Mandali.
11. Mr. K. Bose, Honorary Secretary, Palli Mandali.
12. Mr. H. R. Sen, M.A., B.L., Sub-Divisional Officer, Ranaghat.
13. Mr. N. Mukherji, M.A., B.L., Chairman, District Board, Nadia.

* We publish these Proceedings for three reasons chiefly: (a) because they show the valuable anti-malarial work which is being carried on in Bengal by voluntary agencies; (b) they raise the question of "species control" in malaria; and (c) that of the value of quinine prophylaxis.—(Editor, I. M. G.)

* Howlett, F. M. "Indian Insect Life," pp. 560-564, mentions that the burrows are constructed of bits of algæ.

14. Dr. H. Banerji, M.B., D.P.H., District Health Officer, Nadia.

15. Shams-ul-Ulama Kamaluddin Ahmad, M.A., B.L., Principal, Krishnagar College.

16. Mr. F. J. Gossip, Live Stock Expert, Government of Bengal.

The Conference met after lunch at the residence of Mr. N. Mukherji, Zamindar, Birnagar. In the morning the party had inspected the malaria control work conducted by the Birnagar Palli Mandali, and the records and statistics maintained by it.

The following note written by Mr. K. Bose, Honorary Secretary, Birnagar (Palli Mandali, for expert opinion was placed before the Conference. A copy of this note had previously been sent to the expert members.

NOTE BY THE HONORARY SECRETARY, BIRNAGAR PALLI MANDALI.

I. *Carrier species and proposed line of action.*—This is discussed at pages 45 to 50 of my report on Malaria Control at Birnagar for 1927. Through the kindness of Dr. C. A. Bentley 1,843 anopheline mosquitoes out of 2,647 collected from Birnagar were dissected for sporozoites and zygotes at the Malaria Research Laboratory at Krishnagar during the period July to December 1928. A summary of the reports received is given below:—

Species.	Number collected.	Number dissected.	Number found infected.	Percentage of infection.
<i>A. fuliginosus</i>	977	787	1	0.12
<i>A. pallidus</i>	295	234	nil	..
<i>A. philippinensis</i>	591	458	13	2.83
<i>A. sinensis</i>	117	74	nil	..
<i>A. barbirostris</i>	4	4	nil	..
<i>A. varuna</i> (<i>funestus</i> or <i>listoni</i>)	31	21	nil	..
<i>A. pseudo jamesi</i>	135	99	nil	..
<i>A. vagus</i>	400	163	nil	..
<i>A. rossi</i>	97	3	nil	..
TOTAL	2,647	1,843	14	..

Dr. P. Sur, M.B., D.P.H., who made the dissections, says that in nature *A. philippinensis* has also been found to contain the malaria parasite around the rural areas of Krishnagar, which is 12 miles from Birnagar.

It is for the experts to say whether any definite conclusion can be arrived at on the basis of these findings, and on the knowledge available elsewhere in India or other countries as to what species are malaria carriers at Birnagar. The report of the Krishnagar Research Laboratory establishes *A. philippinensis* to be a carrier. *A. varuna* (*funestus* or *listoni*), so far as my information goes, is admitted by all specialists as a virulent carrier of malaria, and notwithstanding the paucity of collection of adult mosquitoes and the limited number of pools in which it was found to breed it should obviously be dealt with. But difference of opinion exists among experts in India as regards the other species, particularly *A. fuliginosus*. If we have to deal with any of the three species, viz., *fuliginosus*, *barbirostris* and *sinensis*, we shall have to apply oil to practically all the tanks and pools at Birnagar throughout the year. Our present policy has been to follow this up as far as our resources will allow. It is for consideration whether any deviation from this policy should be made. Mr. R. Senior-White, F.R.S.E., Malarialogist, B. N. Railway, Calcutta, expressed the opinion in July 1928 that we might well leave these species alone and concentrate

attention on *A. funestus* (*varuna*) only. He asked us to make a more careful and extended survey for this species at Birnagar. Unfortunately we were unable to find this species in large numbers either in the adult stage or in larval stage during 1928. It is said that it is not easy to catch this species as it often eludes observation. But why should its larvæ also elude us? In this connection I may point out that although we found only 4 specimens of *A. barbirostris* out of 2,647 adult Anopheles collected during the six months ending December 1928, we saw this species breeding in abundance in tanks and pools over a wide area at Birnagar. Considerable caution is therefore necessary in coming to a judgment.

Larval identification made by Mr. M. O. T. Iyengar, F.Z.S., Government Entomologist, since 1927 shows the presence of the following species at Birnagar: *A. fuliginosus*, *A. pallidus*, *A. philippinensis*, *A. sinensis*, *A. barbirostris*, *A. varuna* (also called *funestus* and *listoni*), *A. tessellatus*, *A. pseudo-jamesi*, *A. punctulata*, *A. vagus* and *A. rossi*.

We found *A. varuna* (*funestus* or *listoni*) larvæ in 4 tanks and pools only, and *A. philippinensis* larvæ in 13 tanks and pools. It is likely that the larvæ of the latter species will be found in many other tanks and pools in the course of our future survey, as *A. philippinensis* and *A. pallidus* were grouped under a single head *A. fuliginosus* during our larval survey of 1927 and the greater part of 1928. The Government Entomologist, who made the identification, tells me that these species were differentiated from *A. fuliginosus* only recently. Consequently a resurvey of the breeding places is necessary in order to locate definitely *A. philippinensis* and *A. pallidus*. Thanks to the co-operation of the Public

Health Department, Bengal, the survey work is being continued.

If we could determine the carrier species of Birnagar and concentrate attention on them alone, we could avoid wastage of money which is inevitable under the present system. Perhaps a decision on this point can only be made in the light of the results obtained which are stated below.

The result of observations on the splenic index of children at Birnagar undertaken by the Bengal Government shows that it fell from 80 per cent. in 1925 to 24 per cent. in 1927 and 17 per cent. in 1928. We claim that this reduction is due to our effective quinine campaign and not to mosquito control work. This is fully explained in my report for 1927. The Government Report for 1928 also corroborates this view:

	Number of children examined.	Spleen rate (July 1928). Per cent.
Quinine and non-quinine total	311	17
Quinine cases	235	5.5
Non-quinine cases	76	50

It will thus be observed that the anti-larval measures have not produced any tangible results. We had to leave off oiling 2.6 miles out of about 8.6 miles of

water-edge during the rainy season owing to public opposition. We have been able to do away with much of this opposition from November 1928 only, and since then have been applying oil to most of the tanks hitherto left out. It is premature to say if this extended operation will cause any difference in the results next year. Besides the above the canal and the *bhil* and a large silted up tank called Purana Dighi were left out of the scope of our operations.

be advisable to open up the heads of the canal near the Hooghly to allow more water into your area seems to be doubtful."

Rai Bahadur S. N. Banerji, Superintending Engineer, Government of Bengal, Irrigation Department, who was informally consulted, expressed the opinion that the sharp concave bend of the Hooghly at the junction of the channel is not favourable to the scheme of opening up the head for the purpose of bringing in silt-

No. 1.—Paris Green demonstration by blowers.

II. *Question of dealing with Baromeshey Canal and Chaka Bhil.* I have said before that we were not able to deal with the canal which forms the southern boundary of Birnagar, and the *bhil* on the south-west. We have already carried out a survey of the entire length of the canal from the Hooghly to the Churni with a view of seeing if it is possible to flush the *bhil* and the canal with the silt-laden water of the Hooghly or the Churni during the rainy season—*vide* my report for 1927.

Dr. C. A. Bentley expressed the following opinion in June 1928:

"The efforts of the Mandali for the proposed improvement of the local canal system for stamping out malaria from Birnagar are most desirable. It is quite possible that mosquitoes breeding within the Chaka *Bhil* and the Baromeshey *Khal* migrate into Birnagar causing intense malaria. The mosquitoes, if they do not get food near their breeding-places, will certainly travel a long distance in search of their food. It is a known fact that if silty water can be introduced in such breeding swamps, the output of mosquitoes can be brought to a minimum. The Palli Mandali has adopted the right course, in making a survey of the levels of the channel and the *bhil* with a view to ascertaining whether flushing with silt-laden water from the Hooghly river would be possible."

Major J. A. Sinton made the following observation about the same date:

"If I may make some remarks on your paper (*Malaria Control at Birnagar for the year 1927*) I would say your suggestion about getting the Baromeshey Canal cleared in the vicinity of Birnagar seems sound, because it is possible that if this drainage channel was cleared it would allow free exit of water from the town and so lower the level of the subsoil water generally and abolish a certain number of breeding-places. This is a question to be investigated by an engineer. Whether it would

laden water. The reason advanced was that the rapid erosion of the bank at this particular spot would cause a heavy deposit of silt inside the channel and at its mouth, thus involving a considerable recurring annual expenditure on silt clearness. Besides, there appears to be some practical difficulty as the surrounding areas will be submerged which will necessitate award of compensation to the cultivators. On the other hand it may be possible to deal with the Baromeshey Canal and the Chaka *Bhil* without much difficulty. Consequently it is proposed to split up the scheme into two portions and to deal with the later first. It will be for the experts to say what precautions should be taken to control mosquito-breeding in the canal and the *bhil* when excavation work is undertaken. At present the breeding of anopheline mosquitoes goes on in the entire surface of the *bhil* throughout the year, and in the canal so long as the water remains.

Our resources are limited; and I doubt very much whether we shall be able to raise sufficient money to continue our present anti-larval campaign and re-excavate the canal in addition. It is for consideration whether we should be justified in suspending the general application of oil to tanks and pools, except those that are found to contain larvæ of carrier species, and in concentrating attention towards the re-excavation of the canal.

III. *Question of dealing with the Purana Dighi.* The Purana Dighi is a silted up tank occupying about 11 acres of land on the east side of Birnagar. The Birnagar Municipality intends to grow a fodder crop there as part of its scheme for pasturage. As this scheme is not likely to materialise at an early date it seems desirable that the Palli Mandali should deal with this breeding-place without delay. The only effective way of dealing with it seems to be to drain out its water, if possible. This will cost a good deal of money as a trench will have to be dug for about three-fourths of

a mile. If this course is decided upon a level survey will be necessary.

IV. *How to prevent fish from getting tainted with kerosene oil.* A mixture of crude oil called "pesterine" and refined oil called "solar oil" is sprayed on water edges up to a distance of four feet from the bank by a

Almost all our tanks are stocked with fish. The fish swallow up the oil and imbibe its smell and retain it even when cooked for the table. The small varieties of fish cannot be eaten owing to the smell, while the larger varieties, such as *rahu*, imbibe the smell in their heads which have to be rejected. During the last five years we

No. 3.—Spraying from a boat.

movement of the nozzle of the sprayer from right to left and then to right and so on. This is done thrice a month by a trained coolie who walks along the bank as fast as the slope of the ground will allow. Sutton's Four Oaks' sprayer is used in spraying and gives a good spray. The tanks have great depths but they contain shallow water, as the subsoil water is found at a depth of 30 feet from ground.

applied oil to a limited number of tanks, but since November 1928, we have been applying it to most of the remaining tanks. This step on our part will result in spoiling the fish in all our tanks, and it seems doubtful whether we are justified in causing serious injury to the fishing industry of the village. The Society is not aware whether any similar result has been noticed elsewhere in India. It is understood that the other societies in Bengal

do not apply oil to tanks owing to an erroneous impression that fishes of small variety eat up all larvæ. We have found small fishes and mosquito larvæ thriving side by side in natural conditions, even when the tanks* are kept free from weeds.

V. *Advisability of using Paris green in tanks.* At the suggestion of Col. J. D. Graham, C.I.E., I.M.S., Public Health Commissioner with the Government of India, Paris green has been tried as a larvicide by way of experiment in portions of our canal and in a number of stagnant pools since July 1928. As its cost is considerably less than that of oil, much money can be saved if it is used in the canal and small stagnant pools during the rainy season. It is proposed to use Paris green in the canal during the ensuing rains by blowers from a light boat, which has been constructed by the Society. Much of the opposition from the public to the oiling of tanks can be eliminated if we substitute Paris green for oil.

It appears from our correspondence with Major J. A. Sinton that he does not consider Paris green to be injurious to human beings and cattle. He has apparently based his knowledge on Hackett's pamphlet. Dr. G. Bose, our Chief Medical Advisor, says that as arsenic is a cumulative poison Paris green should not be applied to tanks used for bathing and drinking purposes. The question of its application to tanks may therefore be considered.

VI. *Should mass quininisation be resorted to for an indefinite period?* The Palli Mandali took up the administration of quinine and cinchona on a large scale in September 1926. As the drugs are supplied in tablet form, the dosage administered is as follows:—

Curative—4 pills of Quinine (4 grs. each) per day, Cinchona (3½ grs. each) 2 in the morning and 2 in the afternoon for the first 3 days, and 2 pills from the 4th day for a period of 3 months, or longer if necessary.

Preventive—2 pills of Quinine (4 grs. each) per day, Cinchona (3½ grs. each) morning and afternoon for 2 days. Repeat the same at intervals of 4 days, so long as the village is not made malaria-free.

There was some opposition from a section of the public last year to the continued administration of quinine and cinchona by the Palli Mandali, particularly during the winter and summer months when malaria was not much in evidence. Even some educated gentlemen, including a few officials, view with apprehension the prolonged use of quinine by the general population. They fear that such administration is bound to cause ill-effects in future. So far as the Palli Mandali is aware no ill-effect has been noticed in a single case as yet; and we took our stand on the assurance given by Sir Malcolm Watson in his book on the *Prevention of Malaria*, which runs as follows:

Ill-effects of Quinine. It has been with a due sense of responsibility, and no little anxiety, that I have found myself the instrument in causing large numbers of people

to take quinine for prolonged periods in doses which appear excessive to many, and doses which year to year tend to increase in amount. I have watched the effect of its administration with care, and if it is producing any ill-effects, they are of such a nature as not easily to be detected—at any rate I have not detected them—and they are of infinitely less consequence than malaria."

It will be noticed that the dosage prescribed by the Palli Mandali is the minimum that can be administered with efficacy.

Following the advice given by Professor Grassi of Italy we have continued the administration of quinine even during the dry months when of the two hosts, man and mosquito, the former alone is present. If we can reduce the human infection during this period to any great extent, the incidence of malaria during the epidemic season may be expected to decline. It was therefore thought inexpedient to discard this important weapon in our fight against the disease. As the Society's responsibility in this matter is very great, the opinion of the experts is sought on the desirability of continuing the quinine campaign throughout the year. Should the experts advise in the affirmative after an examination of our system of administration, a pronouncement to that effect will allay public anxiety, and help the Society in pushing on the campaign.

Sir Malcolm Watson explained at length concerning all the points raised in the above note, except that concerning the Purana Dighi, which could not be visited for want of time. A lively discussion ensued. The following resolutions were then adopted.

RESOLUTIONS.*

Resolution I.—That if the Palli Mandali with the help of the Public Health Department, Bengal, finds it possible to locate definitely the breeding-grounds of *A. philippinensis* these should be dealt with by the new brand of pesterine as used in the Malay States.

Resolution II.—That the water edges of all other tanks be kept free from vegetation periodically and that the application of oil to them be reduced in order to prevent the fish from acquiring an unpleasant smell.

Resolution III.—That all other stagnant pools be periodically dealt with by the new brand of pesterine or Paris green as may be found convenient.

Resolution IV.—That the present system of quinine administration to the general population be continued.

With regard to the improvement of the canal system of Birnagar from the Hooghly to the Churni, Sir Malcolm Watson was of opinion that this was a large work to be carried out by Government after the enquiry suggested by him. It was resolved:

Resolution V.—That pending the re-excavation of the canal Paris green be applied to water surface by blowers.

Sir Malcolm suggested that the records of malaria control work should be kept in duplicate. The Secretary, Palli Mandali, agreed to keep a duplicate set of records in Calcutta.

* The draft of these resolutions was approved and signed by Sir Malcolm Watson in Calcutta on the 26th February, 1929.

* Natunpekur (No. 162) re-excavated by the Birnagar Municipality in March 1924 at a cost of Rs. 1,663. Leased out for fish cultivation at an annual rent of Rs. 60. Water examined on 17th March and 21st July, 1928, when *A. fuliginosus* and *A. sinensis* larvæ were found.

Bagdipokur (No. 154) re-excavated by the Birnagar Municipality in April 1926 at a cost of Rs. 1,198. Leased out for fish cultivation at an annual rent of Rs. 35. Periodical examination of water showed breeding of the following species:

16th February, 1927 ..	<i>A. rossi</i> .
25th October, 1927 ..	<i>A. rossi</i> , <i>A. barbirostris</i> and <i>A. sinensis</i> .
1st November, 1927 ..	<i>A. sinensis</i> .
20th January, 1928 ..	<i>A. sinensis</i> and <i>A. pseudo-jamesi</i> .
17th March, 1928 ..	<i>A. fuliginosus</i> and <i>A. sinensis</i> .
15th November, 1928 ..	<i>A. rossi</i> .

After the Conference was over the party proceeded to the Municipal Office where an address of welcome was presented to Sir Malcolm Watson by Mr. N. Banerji, Chairman, Birnagar Municipality.

A Mirror of Hospital Practice.

A CASE OF ACUTE ASCENDING (LANDRY'S?) PARALYSIS.

By R. VISWANATHAN, B.A., M.B., B.S.
Assistant Surgeon, Government Headquarters Hospital, Coimbatore.

THE rarity of the above disease in these parts is the excuse for my reporting the following case:—

On 14th February, 1929, a Hindu male, aged 45 years, was admitted to the District Headquarters Hospital, Coimbatore, complaining of inability to walk, retention of urine and constipation.

History.—Two days previous to admission he felt a slight heaviness of the lower limbs which the next day became absolutely paralysed. From the evening previous to admission, he had not passed urine or motions.

Examination.—Lower limbs were absolutely flaccid with loss of all reflexes, absence of Babinski's sign, and absence of any sensory changes. At the time of admission there was paresis of the upper limbs, though he could still move his fingers and wrists. All the other systems were quite normal excepting for slight rapidity of the pulse and general malaise.

The bladder was emptied, a brisk purge was given and stimulants were administered. The morning after admission the patient died of respiratory failure. He never lost consciousness till the end.

The diagnostic evidences which point to the possibility of the case being one of Landry's paralysis are its rapidly spreading nature, absence of any sensory disturbances, bilateral affection, loss of all reflexes both superficial and deep, and death three days after onset due to respiration failure. The difficulty in emptying the bladder with consequent retention was evidently due to general weakness of the trunk muscles and not as a result of inherent disturbance of the sphincter action, which is rare in Landry's paralysis. Acute spreading myelitis and intrathecal hæmorrhage are ruled out by the absence of any sensory disturbances, while age and absence of severe general symptoms are against the possibility of acute anterior poliomyelitis.

I must thank Col. F. C. Rogers, I.M.S., for kindly allowing me to report this case.

A CASE OF "GLANDULAR FEVER."

By F. H. B. NORRIE, M.D., Ch.M., F.R.C.S. (Edin.),
Medical Officer, The Angus Company, Limited, Angus P. O., Hooghly Dist. (Bengal).

I was called to see Mr. O. on 19th March, 1929, and found he had been feeling out of sorts since the previous day. Vague aches and pains all over his body, loss of appetite, slight fever, glands in posterior triangles of neck, both sides, axillary and inguinal glands enlarged, painful and tender to touch. Feels his neck stiff.

On questioning he stated he had been out shooting in the jungle on Saturday, 16th. Blood taken at night was negative for malarial parasites and filaria.

20-3-1929.—Glands less painful.

21-3-1929.—Glands subsiding, less tender.

23-3-1929.—Glands all subsiding, feeling better.

24-3-1929.—Rise in temperature last night accompanied by painful enlargement of pre-auricular glands.

27-3-1929.—Temperature normal for 2 days. Patient feels fit for work. All glands still palpable but no longer painful or tender.

No rash at any time. Salicylates and salines were exhibited throughout.

This would appear to have been a case of glandular fever. Short incubation period, approximately 48 hours in this case, duration 7 days. painful adenitis—first described by Pfeiffer in 1884. Puncture of the enlarged glands is reported to be negative. This was not done in this case.

A BENIGN SPINAL TUMOUR.

By P. McRITCHIE, M.C., M.D., M.R.C.S., L.R.C.P.,
Surgeon Specialist, Iraq Health Service, Basrah, Iraq.

THIS case presents nothing of exceptional interest, except that it is illustrative of the length of time that these cases may go on, causing years of pain and invalidism.

The patient a man of about 35, had pain for seven years in both legs, increasing in violence greatly in the last seven months. Weakness had gradually increased until he was unable to walk unaided. Sphincter control was lost and impotence was a symptom. He suffered

from a modified Brown-Sequard syndrome, which appears to have been more marked earlier.

Knee jerks were absent.

His Wassermann reaction was negative.

I injected lipiodol in the lower dorsal region rather than the cisterna, as the root pains did not extend above the pubes. An x-ray examination showed the shadow as seen in the upper part of the accompanying picture. I injected

There was no history of syphilis, and a comprehensive anti-syphilitic course effected no improvement.

His lungs were sound and there was nothing wrong with his urine.

some more lipiodol between the 4th and 5th lumbar vertebræ and got the picture as shown.

At operation we found an extosis compressing the cord in the 4th lumbar

vertebra. It was removed without extraordinary difficulty.

The result has been to a considerable extent satisfactory. His urinary sphincter regained its function, but the patient is very constipated. His pain has gone but he can only walk with crutches. His thigh muscles are good, but the leg muscles are, I am afraid, beyond repair.

QUININE ABSCESES.

By CAPT. MOHD. AJMAL HUSAIN, M.B., B.S., P.C.M.S.,

*Medical Officer In-charge, Canal Dispensary,
Rasul (Gujrat), Punjab.*

MRS. H., Bengalee Christian, aged about 40 years, had intramuscular injections of quinine in the gluteal region given by some doctor at Chittagong about 14 years ago. Fever gradually disappeared after these and the patient has been in good health ever since, except for other minor ailments. Some time after the injections she says she felt two small lumps in the right buttock. These, however, were not painful and have been there all these years without any inconvenience or discomfort to the patient. During the last month without any apparent cause both these lumps gradually became bigger in size, were painful, red and hot with some constitutional disturbances in the way of slight rise of temperature and difficulty in walking about. On examination both swellings were found to be inflammatory in nature with deep fluctuation. Operation was done under local anæsthesia on the bigger swelling and a fair sized area of necrotic tissue mixed with pus was scraped away embedded deeply in the substance of the gluteus maximus. The wound thus left was very unhealthy with thick, irregular ragged, undermined edges. It had to be scraped away three times on different occasions before healthy granulations appeared. The other swelling is so far of the same size and palliative measures such as belladonna plasters and antiphlogistine are being applied with the hope that it may still resolve, or at least its inflammation be kept under control till the wound left from the first swelling has healed up completely.

The case is of interest on account of the unusually lengthy interval (14 years) that elapsed between the injections and the development of these abscesses.

A CASE OF PSUEDO-PREGNANCY.

By P. SHARMA, M.B., B.S.,

State Surgeon, Dhar, C. I.

A FEMALE (H. B.) aged 18 years, married four years ago, was admitted to this hospital

for delivery. The relatives gave the history of her being in labour for the last two days and, being declared unmanageable by a *dai*, brought her to the hospital.

Abdominal examination.—Abdomen distended to a level $2\frac{1}{2}$ inches below the ensiform cartilage.

Swelling.—Tense and somewhat compressible.

Fætal parts.—Not palpable.

Fætal heart sounds.—Not audible.

Vaginal examination.—A conspicuous bulging about the size of a small orange was visible at first sight between the two labia. It was continuous above with the vestibule, below with the fourchette and on the sides with the labia minora. There was a small hole near the right labium discharging darkish, viscid fluid (of venous character). The vaginal protrusion was elastic, getting tenser on pressing the abdominal tumour.

History.—The patient gave no history of menstruation and previous labour. Her abdomen began to distend about a year ago. She and her relatives thought she was pregnant. This idea of theirs was confirmed by an untrained *dai*. When the patient was thought to have completed 10 months she was shown to another *dai* who declared that she was in labour and advised her to go to the hospital. (The patient had no pains.)

Inference.—The vaginal protuberance was an imperforate hymen. The *dai* under the impression that the head was quite low and that the tense bulging membranes were obstructing the further progress of the labour, artificially ruptured the hymen as a means to bring her difficulty to an end. But being confused by the sight of the bloody discharge through the rent, she advised the relatives to remove her to the hospital.

The abdominal and the vaginal tumours were due to the retained menses (cryptomenorrhœa).

Operation.—The hymen was excised under chloroform, and nearly five pints of menstrual fluid taken out. On examination the internal organs were all found to be normally developed except the uterus which was enlarged and flabby. No signs of peritonitis were detectable. The patient recovered completely in two weeks.

Points of interest.—

(1) The certainty of the patient, her relatives and the *dais* about the pregnancy.

(2) The medico-legal importance of handling such cases. The operation was performed in the presence of her chief relative in this case.

(3) Absence of any infection considering the period of retention.

Indian Medical Gazette.

JUNE.

THE LIFE-HISTORY OF *ENTAMŒBA HISTOLYTICA*.

OUR present-day knowledge of the "amœbæ living in man" is very largely due to the pioneer researches of Mr. Clifford Dobell, M.A., F.R.S., Protistologist to the National Council for Medical Research of Great Britain. Mr. Dobell is a master of technique, and a most conscientious and careful worker; he publishes nothing that is not mature and well considered, and he has been studying the amœbæ living in man for some fifteen or more years.

In 1924, Boeck and Drbohlav made their now classical announcement that they had succeeded in obtaining cultures of *Entamœba histolytica* *in vitro*. It immediately became obvious that this very important discovery would place in the hands of research workers new methods of studying the human entamœbæ and of working out their life-cycles. The technique of Boeck and Drbohlav was soon improved upon by Dobell and Laidlaw (1926), and with suitable cultural methods now available Mr. Dobell immediately commenced the study of the life-history of *Entamœba histolytica* *in vitro*. In *Parasitology* for December 1928 (Vol. XX, No. 4, p. 357), he publishes his first report on this subject—a description of the complete life-history of *E. histolytica* as observed in culture. This paper is a model of what a report on research work should be; it is the result, not of a few weeks of sketchy experiments, but of years of most careful and conscientious work, well considered, well written, and most exquisitely illustrated with colour plates. Further, this report is the first of a series which is promised for future publication, and Mr. Dobell's further papers—especially the one dealing with the general biology of *E. histolytica*—will be awaited with great interest by all laboratory students and research workers. The present paper clears up so many points that were in doubt, and is so authoritative that it should be studied in the original by all interested in the subject.

The strains used for this work were derived both from man and from the monkeys *Macacus rhesus* and *Macacus sinicus*. After many years of investigation of the subject the author has arrived at the conclusion that *E. histolytica* of man and the morphologically identical entamœba of monkeys are one and the same parasite, and both behave in an

identical manner in culture. The first step in this research was to obtain a pure line strain of *E. histolytica* showing no possible admixture with any other amœbic species; this was accomplished by passage into kittens, in which the strain produced typical amœbic dysentery, and by prolonged observation over some years of the host from which most of the material for study was taken—a *Macacus rhesus*. As the author points out, "to obtain constant and predictable results it is essential (1) to work with a pure strain of amœbæ; (2) to study properly controlled stages only (i.e., amœbæ or cysts—not unknown mixtures); (3) to make certain that the accompanying bacterial flora is invariable; (4) to employ a suitable and standardised medium for all cultures; (5) to maintain an unvarying temperature of 37 to 38°C. throughout. Results obtained by any less rigorous technique, and without attention to the precautions indicated, have—in my experience—little or no scientific value."

The complete life-history of *E. histolytica* consists of four phases. First, the phase in which the amœba is actively motile and dividing by binary fission; this is commonly referred to as its vegetative phase, but Dobell prefers the much more accurate term "trophic amœba" for this phase. Secondly, the phase just prior to encystment, which may be termed the "pre-cystic amœba." Thirdly, the phases of encystment. Fourthly, the phases of excystation, which may be referred to as the metacystic phase. The result of Dobell's researches is that he is now able to produce any one of these phases at will in his cultures by suitable modifications of the environment.

The trophic phase is already very well known. It is seen in its most typical state in a perfectly freshly passed amœbic dysenteric stool. In the monkey, however, *E. histolytica* appears never to invade tissue; it lives in the lumen of the gut and ingests bacteria as food-stuff. That such amœbæ are capable of invading tissue, however, is shown when they are passaged into kittens, in which animals these strains produce typical acute amœbic dysentery. In culture the amœbæ also live upon bacteria, and, if rice starch is added to the medium, they ingest starch particles to excess, often becoming so stuffed with starch particles that the nucleus may be distorted by the pressure of ingested grains. The nuclear structure is true to the "*histolytica* type" previously described by Dobell (1919).

In its active trophic phase, whether in culture, in the lumen of the monkey's intestine, in the mucosa of the colon in infected kittens, and in man, the amœbæ multiply by equal binary fission. During division chromosomes appear to be formed, and the process is a close approximation to typical mitosis as seen in cells

of the Metazoa. The nuclear membrane is retained intact throughout the process, however, and the chromosomes are so minute that it is difficult to be certain of their true number. "At present," writes Dobell, "I believe that the division is a mitosis of a peculiar kind, and that the chromosome number is probably constant; but what it really is I do not know." Recently divided daughter amœbæ usually show a karyosome which is not central, and a variable number of rather indefinite granular structures in the area between it and the peripheral chromatin. During division the amœba is almost motionless, and pseudopodial activity only recommences when the daughter amœbæ have finally separated from one another.

Just prior to encystment, during the precystic phase, the amœbæ round up and become smaller than in the trophic phase. The cytoplasm becomes free from all food-inclusions and usually contains diffuse glycogen and occasionally chromatoid bodies. Both glycogen and chromatoid substance are in the nature of food reserve supplies, destined to nourish the amœba during its phase of encystment.

A cyst wall is next secreted, and nuclear division—by a process similar to that in the trophic phase—sets in. During the early phases of encystment there may be considerable glycogen within the cyst; it is usually diffuse, sometimes however contained within a definite glycogen vacuole, though the glycogen vacuole never reaches the enormous size so characteristic of the cyst of *E. coli* at its binucleate phase. Later, as the cysts become more mature, the glycogen is used up, and the mature quadrinucleate cyst contains little or no glycogen. As the cyst matures the massive chromatoid bars, chunks and masses become more and more prominent, and they are the most characteristic feature of the cyst of *E. histolytica* as seen in a perfectly freshly passed stool. After the stool has been passed, however, they rapidly break up, fragment, and diffuse, and they may not be seen in cysts studied in a stale stool. The cysts vary in diameter from about 10 μ to 16 μ with an average diameter of 13.5 μ . In cysts in culture the shape is always spherical, and the oval or somewhat distorted cysts sometimes seen in human fæces are not present. The time occupied in passing from the precystic to the uninucleate encysted phase is about two hours; whilst the cyst takes about six hours longer to mature to the quadrinucleate phase. Very occasionally nuclear division overshoots the mark and an abnormal cyst with eight nuclei is produced.

The future life-history of the cyst as passed in the fæces all depends upon environment. In desiccating fæces exposed to the full heat of the sun the cysts die off rapidly; if they reach a water supply, however, they will

survive. "In any liquid which is not injurious—such as culture-medium, distilled or tap water, or Ringer's fluid—mature cysts can live at ordinary room temperatures for two or three weeks, and exceptionally for four or even five. At 37°C., however, they can survive in water for only a few days at most. Drying kills them instantly." (The importance of these observations in connection with the spread of amœbic infection in the tropics is at once apparent. The stool passed by a villager on to the surface of a sun-baked field is not dangerous; it is when the cysts gain access to the village tank or water supply that danger occurs. Also one is led to wonder whether a dry conservancy system may not be preferable for cities in the tropics to a water conservancy system.)

Once the cyst is passed, it immediately commences to live upon and use up its food-reserve supplies, i.e., its glycogen and chromatoid substance. Uninucleate and binucleate cysts do not survive, whilst quadrinucleate cysts appear to pass into a resting state, though occasionally a further nuclear division may take place, resulting in the formation of from 5 to 8 nuclei.

Excystation of the cyst will only take place at body temperature.—This is perhaps the most important point in the whole of Dobell's memoir, for it indicates how highly specialised is *E. histolytica* for parasitising man. In order to observe the process of excystation in cultural material everything—cultures, microscope, slides, etc.—has to be taken into the "hot room" which is maintained at body temperature, 37° to 38°C. (In studying the process of excystation Mr. Dobell had to spend days and days in the "hot room" of the Medical Research Institute at Hampstead, and the present writer, who was privileged in 1928 to see Mr. Dobell's original preparations, both the fresh *in vivo* ones and the stained material, can sympathise with him in the extremely trying conditions which he had to endure in carrying out this research. The atmosphere in the "hot room" at Hampstead is rather like that of Calcutta in September, but without a fan.)

The chief importance of this memoir is its full account of the process of excystation of *E. histolytica*—the metacystic phase, as the author terms it. There has been much wild speculation in the past with regard to this process, and the publication of many pseudo-observations and papers which will now pass into the region of the ephemeral. This account is clear, full, detailed, authoritative, and accurate. In the course of time we hope that it will be incorporated in the textbooks on tropical medicine. The partial account of the process of excystation published by Yorke and Adams (1926) is particularly unfortunate, because of its inaccuracy. Still more unfortunately this account has been copied with its

illustrations in Thomson and Robertson's *Protozoology* (1929), the textbook in protozoology for students at the London School of Tropical Medicine, as Dobell's memoir was not available to these authors when they were compiling their book.

The production of four nuclei within the cyst obviously appears to indicate a method of multiplication within the cyst, and one would naturally expect that the progeny finally liberated from the cyst would be four amoebulae. What actually happens, however, is something entirely different, something which could never have been guessed, and which Yorke and Adams did not realise, although their figures clearly show the combinations within the emergent mass of protoplasm of N and n , to which we shall soon refer.

Cysts taken into the hot room do not hatch until their glycogen and chromatoid substance has been used up. Shortly after this has occurred, streaming movements begin within the protoplasm within the cyst wall, and the protoplasm is gradually retracted and withdrawn, leaving a clear space filled with liquid between the cyst wall and its protoplasmic contents. Pseudopodial activity now commences and fine pseudopodia are thrust against the cyst wall at various places. The movements in general are of a slow but sustained rotatory character, with protrusion of small pseudopodia of clear ectoplasm thrust against the cyst wall, as if searching for a means of exit. This process goes on for half an hour or longer. Finally an exceedingly minute pore forms in the cyst wall. (It is not a huge jagged rent, as depicted by Yorks, and Adams, but a pore so minute as to be almost invisible, even in stained specimens.) Through this a tiny hernia-like bud of cytoplasm is protruded into the outside environment, and then again withdrawn inside the cyst wall.

A most curious to and fro pseudopodial activity next ensues. Increasingly large hernia-like protrusions of protoplasm are extruded through the minute pore and then withdrawn again. At times almost three-quarters of the contents of the cyst may be extruded, only to flow back again within the cyst wall. Occasionally, but not usually, the amoebic mass tries to escape through two tiny pores and not one. So tiny is this pore that in stained specimens it may be observed that the nuclei are constricted into an hour-glass shape as they pass through it, though they immediately recover their spherical shape as soon as they are free of the constriction. (This tiny pore is presumably formed by a solution of the cyst wall by a ferment secreted by the amoeba, as it is certainly not present in the mature cyst prior to excystation.)

Sooner or later the entire mass succeeds in emerging from the cyst. As it does so, as a rule a "tail" of protoplasm is nipped off and remains within the cyst wall. Empty cyst walls from which the contained amoebae have emerged are very characteristic of cultures studied in the fresh state (at body temperature) at a late stage of excystation.

The emergent mass of protoplasm, which we may term an "amoeba" (though the phrase is perhaps not quite an accurate one) soon shows considerable pseudopodial activity. The animal on emergence is evidently very hungry, for it commences to stuff itself with grains of rice starch, and rapidly grows to about twice its original diameter. The entire process of excystation may take place within fifteen minutes, but it usually takes from half an hour to an hour. The four nuclei in the emergent mass of protoplasm always show a special tendency to agglomerate together towards the anterior pole of the amoeba, a fact which was also noted by Yorke and Adams.

The metacystic stage is one which can be clearly understood only if close attention is paid to the two text diagrams included in Dobell's paper, both of which are here reproduced. The essential steps in the process are as follows:—

"(1) The metacystic development is a process of subdivision only, and no conjugation or fusion of individuals or nuclei occurs.

(2) The newly hatched quadrinucleate amoeba does not divide into uninucleates directly, but by successive stages.

(3) *The original quadrinucleate amoeba does not finally give rise to four uninucleates, but to eight.* This is the key to the whole process.

(4) Every division of the cytoplasm is preceded by a nuclear division.

(5) Each of the four original nuclei divides once during the metacystic development—and once only.

(6) Between any two successive fissions of the cytoplasm a variable period of growth supervenes."

Following Dobell, let us represent the cystic nuclei within the emergent mass of protoplasm as $N.N.N.N.$ Then the final progeny may be represented as $n.n.n.n.n.n.n.n.$ Each N sooner or later divides into $n.n.$, and eight amoebulae are finally produced. The cystic nuclei ($N.N.N.N.$) can always be distinguished from the daughter nuclei ($n.n.n.n.n.n.n.n.$) by their much larger size. Throughout, however, the nuclear structure remains true to the "histolytica type," and division is by a process of modified mitosis.

In the production of eight little daughter amoebulae ($n.n.n.n.n.n.n.n.$) from the newly excysted amoeba ($N.N.N.N.$) binary fission of the cytoplasm may lag behind division of the nuclei. Even tripartite and very rarely quadripartite fission of the cytoplasm may

take place simultaneously. The result is that there are no less than fourteen different ways in which a daughter amœbula (n) can be produced from the excysted amœba (N). Of these fourteen possible ways, Dobell has seen twelve in his stained specimens, but has failed to encounter two.

The commonest method of division is as follows (Fig. 1). The newly excysted quadri-

Fig. 1.

nucleate amœba is about 11μ in diameter. It creeps about actively for some time and feeds voraciously, its diameter increasing in about two hours to about 16μ to 20μ . The four nuclei (N.N.N.N.) remain aggregated together towards the anterior pole. Next one of the nuclei divides ($N = n.n.$). As this happens the nuclei seem to lose the tendency to aggregate together and may become widely separated, whilst the daughter nuclei ($n.n.$) usually draw widely apart at the end of division. The cytoplasm next constricts into two, and as a result there are formed two protoplasmic masses with different nuclear structure, one being trinucleate (N.N.n) and the other binucleate (N.N.). In the latter the cystic nucleus (N) next divides into two ($n.n.$); the cytoplasm also divides; and this produces a daughter amœbula (n), and an amœba with two daughter nuclei ($n.n.$). This form next divides into two, producing two daughter amœbulæ (n) and (n). Thus one of the protoplasmic masses which result from the first division gives rise to three daughter amœbulæ,

The second mass (N.N.n) next undergoes a second nuclear division (N.n.n.n.). By cytoplasmic fission following, two daughter amœbæ are formed with nuclear structure $n.n.$ and N.n. respectively. The former produces two amœbulæ (n) and (n). In the latter (N.n.) nuclear division gives rise to three nuclei ($n.n.n.$), and the production finally of three daughter amœbulæ (n), (n), (n). Thus the second protoplasmic mass which results from the first division after excystation ultimately gives rise to five daughter amœbulæ.

Other and less common methods of division are illustrated in Fig. 2. It will be seen

Fig. 2.

that there may be produced a uninucleate amœba containing only one cystic nucleus (N). This can be distinguished from the daughter amœbula (n) by the larger size of its nucleus. The production of eight amœbulæ from the excysted amœba takes from eleven to thirteen hours. The daughter amœbulæ now grow up into typical trophic forms, thus completing the life-cycle.

No evidence was seen at any stage of budding, conjugation, or sexual processes. The aberrant octonucleate cysts hatch normally, but their ultimate fate in cultures could not be made out.

Presumably when the mature cyst of *E. histolytica* is ingested by man, the same process occurs, and eight daughter amœbulæ are liberated. Sellards and Theiler (1924) and Hoare (1926) have shown that the cyst of *E. histolytica* will excyst in the rectum of the kitten, so the process of excystation in man probably takes place in the cæcum rather than in the small intestine.

Dobell's paper is a most notable contribution to the literature, and his readers will look forward to the succeeding papers of the series.

THE INDIAN MEDICAL YEAR, 1928:

CORRIGENDUM.

In the *Indian Medical Year*, 1928, issued with our last number, the paragraphs within brackets on p. 14, first column, lines 11 to 18, should be deleted. We regret that any remarks which we have made should have hurt Dr. H. N. Mukherjee, as we had not the slightest intention of specifically singling out his paper for comment. What we meant to do was to draw attention to the undesirability of duplicating publication of the same article in two or more medical journals.

Our attitude, however, remains unchanged. It is perfectly true—as Dr. Mukherjee has pointed out to us—that even distinguished British workers often duplicate articles in well-known medical journals, but we consider the practice undesirable. A Hunterian oration or some important lecture may naturally be reported by several journals, as a matter of general interest to the profession; but, in the main, duplication is both unnecessary and undesirable; the congestion in medical journals in general is very acute, whilst the review journals can be trusted to broadcast any discovery of importance. (EDITOR, *I. M. G.*)

BINDING OF INDIAN MEDICAL GAZETTE VOLUMES.

Two standard bindings have been devised for the volumes of the *Indian Medical Gazette*—

(1) With red art linen back and corners and green cloth sides.

(2) With red roan leather back and corners and green cloth sides.

Messrs. Thacker, Spink & Co. are prepared to bind the volumes (with or without the advertisements) at Rs. 4-8 or Rs. 5-4 per volume according to which binding is chosen.

Medical News.

BOMBAY MEDICAL COUNCIL.

Proceedings of the meeting of the Bombay Medical Council held on the 18th February, 1929.

1. The Council considered the case of Mr. Naraindas Dharamdas Lalvani, a registered medical practitioner

of Hyderabad (Sind), who had been summoned to appear before the Council on the following charges:—

(1) That he being a registered medical practitioner under the Bombay Medical Act, 1912, on or about the 3rd June, 1927 issued a certificate over his signature that a boy by name Gada Hussain had been under his treatment from the 5th January, 1927 to 5th March, 1927 for pneumonia following diphtheria and was advised to keep away from school on account of the highly infectious nature of the disease;

(2) That the registers of the Government High School showed that the said Gada Hussain attended the school upon all the working days throughout the months of January, February and March except one day in February when he was given leave;

(3) That it thereby appears that he did not in fact treat the said Gada Hussain during the period mentioned as stated in the said certificate and that his said certificate was in fact untrue;

(4) That in his answer dated 28th June, 1928 to the Head Master, Government High School, Hyderabad, Mr. Naraindas stated that the dates of the period of illness were supplied to him by the father of the boy; and

(5) That he has committed a breach of Rule 2 of the Code of Medical Ethics by the issue of the said untrue certificate.

As Mr. Naraindas did not submit a satisfactory explanation of his conduct or express regret for it, the Executive Committee considered that the case was one in which an enquiry ought to be held and directed the Registrar to take steps for the institution of an enquiry under the rules. Subsequently, however, Mr. Naraindas having, before the date of the meeting, submitted a letter in which he admitted his negligence in not verifying the dates entered in the certificate which he granted, and expressed his regret for not having done so, the Council resolved as under:—

"That in view of the appeal by Mr. Naraindas D. Lalvani to forgive, and his admission of having granted an incorrect certificate—which he might have done earlier with grace—the Council do not propose to proceed further with the case, and warn Mr. Naraindas to be careful in future in granting such certificates."

2. The Council resolved to accept for registration as an additional qualification the Diploma in Medical Radiology and Electrology (D. M. R. E.) of the Cambridge University.

3. The Council considered a letter from Mr. D. D. Sathaye, F.R.F.P.S. (Glasg.), requesting to be informed what procedure he should adopt if he wished to get the letters F.C.O. (Fellow of the College of Ophthalmology, Bombay) registered as an additional qualification, under the Bombay Medical Act, and resolved to inform him that the Council were unable to agree to the proposal as their policy is to recognise for registration only such qualifications as are granted by recognised Universities or other regular Corporate Examining Bodies.

4. The Council considered an application from Mr. A. B. Yardi for permission to be registered under section 7 (3) of the Bombay Medical Act and resolved to inform Government that in the opinion of the Council the permission applied for may be granted.

5. The Council considered an application from Mr. R. L. Mungrey for permission to be registered under section 7 (3) of the Bombay Medical Act and resolved to inform Government that as the applicant was not able to produce satisfactory evidence that he was practising medicine in the Bombay Presidency before the 25th June, 1912, he could not be given the benefit of Section 7 (3) of the Act.

6. The Council resolved that the meetings of the Council be thrown open to the press except on occasions when for special reasons cases are heard *in camera*, and that in penal cases full notes of the proceedings be recorded.

7. The Council considered a reference from the Bombay Government communicating, for remarks, a recommendation of the Surgeon-General with the Government of Bombay that Miss Holdforth, a trained midwife and nurse, who has been in charge of the Baker Hospital, Larkana, for the past 18 years and who has been doing the work in the most competent manner, may be granted permission to be registered under section 7 (3) of the Bombay Medical Act, and resolved to inform Government that the recommendation of the Surgeon-General should not be accepted.

8. The Council considered a proposal for inter-provincial registration on a reciprocal basis and resolved to inform Government that in order to give effect to the proposal the following should be added as clause (a) to section 7 (1) of the Bombay Medical Act:—

"Every person who is already registered with any of the Provincial Medical Councils in India with which reciprocity of registration has been mutually arranged, shall on the production of his registration certificate, be entitled to have registered under this Act, free of charge, the qualifications registrable under this Act, which are entered in the said certificate."

9. The Council resolved on consideration of certain further circumstances brought to their notice to drop the proposal to prosecute Mr. R. K. Rawal under the Indian Medical Degrees Act.

10. The Council considered an application from Mr. M. K. Parikh, a medical practitioner of Godhra, for the removal of his name from the Bombay Medical Register and resolved not to accede to his application.

11. The following 6 members were elected by ballot as members of the Executive Committee:—

Khan Bahadur Dr. N. H. Choksy, C.I.E.; Dr. Dinshah M. Gagrati; Dr. Y. G. Nadgir; Sir Temulji B. Nariman, Kt.; Lt.-Col. R. Row, O.B.E. and Lt.-Col. W. M. Houston, I.M.S.

THE AMERICAN MEDICAL ASSOCIATION OF VIENNA.

THIS Association, which has an annual membership of nearly 1,000 medical men who go to Vienna for post-graduate teaching, exists essentially to facilitate post-graduate teaching for English-speaking students at Vienna. As many of our readers know, Vienna is a most important centre for post-graduate medical training, and many medical men from India go there. The post-graduate courses given in English at the University of Vienna are all administered by the Association.

Medical men from India proceeding to Vienna for post-graduate study would do well to communicate beforehand with the American Medical Association of Vienna, Vienna VIII, Alserstrasse 9, Austria.

THE SIXTH POSTGRADUATE COURSE IN OPHTHALMOLOGY, VIENNA, 1929.

THE sixth special course for postgraduate study in ophthalmology will be given between October 1st and December 6th, 1929 under the auspices of the American Medical Association of Vienna at the I and II Eye Clinic of the Allgemeines Krankenhaus, Vienna, Austria.

This intensive postgraduate instruction was first originated in Vienna in 1922 as a result of a suggestion

by Dr. Edward Jackson of Denver to Prof. E. Fuchs. Prof. E. Fuchs is kind enough to participate in the programme. Prof. J. Meller and Prof. K. Lindner, chiefs of the Eye Clinics, have again consented to take an active part. The other lectures will be given by Prof. Lauber, the Docents A. Fuchs, Bachstet and Guist and Assistants Dr. Safar, Dr. Sallmann, Dr. Kronfeld, Dr. Fischer and Dr. Subal. Professors, Docents and Assistants of other departments will deliver lectures in their respective subjects: Prof. Kolmer on comparative Ophthalmology; Prof. Schüller on Röntgen-rays, Prof. Hirsch on the Hypophysis and Sinuses; Docent Kofler on the modified West operation; Docent Fuhs on Radium treatment; Assistant Pollitzer on Embryology.

The course has been so arranged that the field can be covered systematically and comprehensively in the allotted time. A preliminary knowledge of ophthalmology is pre-supposed.

Concerning operations only lectures with demonstrations will be given. In refraction only advanced work will be given. In ophthalmoscopy the non-electric ophthalmoscope will be used.

The entire course is given in English for a minimum of ten, and a maximum of sixteen men. The fee is \$244 per man. Applications with a certified cheque for \$50 should be sent to Docent A. Fuchs, Vienna, VIII, Skodagasse 13. Applications are accepted in order of priority.

Further information can be secured by writing to Doc. Dr. A. Fuchs, Vienna, VIII, Skodagasse 13 or to the American Medical Association, Vienna, VIII, Alserstrasse 9, Café Edison.

THE NORDHOFF JUNG CANCER PRIZE.

THE Dr. Sofie A. Nordhoff Jung Cancer Prize at Munich, for the best work of recent years with regard to cancer investigation, has been awarded by the Commission selected for this purpose to Professor Katsusaburo Yamagiwa of Tokio University.

Professor Yamagiwa and his co-operators have founded and developed the technique of inducing cancer with almost mathematical certainty in experimental animals by abrading the skin of the breast and rubbing in tar. The now extensive literature on experimental cancers of animals induced by tar is based on these primary experiments. Professor Yamagiwa has also carried out researches on the origin of tumour cells, and the best methods of checking their growth under experimental conditions. The Commission for selection of the prize winner consisted of Professors Borst, Doderlein, von Romberg and Sauerbruch.

THE HIMALAYAN JOURNAL.

The *Himalayan Journal* is perhaps not strictly a subject of medical interest, but it will interest those of our readers who live in Himalayan hill-stations, or travel there during the hot weather. The Himalayan Club has recently been formed on the lines of the well-known Alpine Club, and the *Journal* is its official publication. The publishers are Messrs. Thacker, Spink & Co., Calcutta, and the price of the journal Rs. 5 per copy.

The first number was issued at the end of April, 1929. It includes an article by Sir Geoffrey Corbett on the origin and meaning of the word *Himalaya*. An interesting account of the Shyok Dam is contributed by Mr. F. Ludlow, and a discussion on the Indus floods and glaciers by Major Kenneth Mason, editor of the journal. Mr. Hugh Whistler, the well-known ornithologist, describes the birds of Kashmir, and Mr. Kingdon Ward, the explorer, his botanical expedition to the Delei valley in the Mishmi Hills in Assam in 1928.

Other members of the Himalayan Club describe journeys to the Tien Shan, to Nanda Devi, through Spiti and Rupshu, and to the Baspa valley, and

Dr. de Graaff Hunter, the well-known geodesist, discusses the attraction of the Himalaya. Brief but authoritative accounts are given of the chief Central Asian and Himalayan expeditions, such as Emil Trinkler's of 1927-28; Filchner's of 1926-28; the Duke of Spoleto's of 1928-29; and Capt. McCallum's. Himalayan notes and reviews of current Himalayan literature are contributed by Sir Francis Young-husband, Sir Edwin Pascoe, Col. Morshead and other well-known travellers and scientists.

The Journal is very well illustrated, the frontispiece being a beautiful photogravure of K 2, the second highest mountain in the world, by the Duke of the Abruzzi. The journal will make a special appeal to those interested in mountain climbing, as well as to scientific workers in general.

THE BRITISH JOURNAL OF UROLOGY.

We have just received the first number of the *British Journal of Urology*. Up to the present there has been no journal published in Great Britain devoted entirely to this important branch of medical science. The question as to whether there was an opening for such a journal has been answered very conclusively in the first number of this new journal.

The editors, Messrs. Frank Kidd and H. P. Winsbury White, who are supported by a very large and representative editorial committee, are to be congratulated on their first number. This number appears to be all that a specialist journal should be.

The seven original articles deal with a number of different aspects of the subject; two are surgical, "Drainage of the Bladder through the Perineum after Supra-pubic Prostatectomy" by Dr. Andrew Fullerton, and "A Contribution to the Surgical Aspects of Polycystic Disease of the Kidney" by Dr. Maurice Meltzer; one is on x-ray diagnosis, "The Pyelographic Diagnosis of Renal Tumour"; one is on laboratory methods, by P. J. Cammidge and H. A. H. Howard; one might be classed as research, "Routes of Absorption in Hydronephrosis: Experimentation with Dyes in the Totally Obstructed Ureter" by Duncan M. Morison; there is a general article on "Urology in Relation to Gynaecology" by Victor Bonney; and finally a clinical article on "The After-History of a Case of Nephrectomy for Polycystic Kidney" by H. Temple Mursell. There are sections for Notes on Interesting Cases, Urological Hints for Practitioners—the catheter in women is this quarter's subject, and Biochemical Notes—by Geoffrey Evans and H. E. Archer. There is an excellent coloured plate of a museum specimen. Perhaps one of the most practical features of the number is a time-table of urological work done in the principal London hospitals and in a few of the main provincial hospitals; this should prove invaluable to the visitors from the provinces and from other countries. Some 28 pages are devoted to abstracts from current literature; this is a very important feature of the journal. Here we have a minor criticism to make; the name of the journal, the name of the reviewer, the title of the paper and the name of the writer of the paper all appear at the head of the abstract and three out of the four are printed in exactly the same type. Admittedly, it is quite obvious which is which, but the general effect is confusing. The most important point to the reader is the title of the paper; this should therefore appear first, or in distinctive type. The least important is the name of the reviewer; this might well appear at the end of the abstract, or better still let only initials be printed here and acknowledgments be made from time to time elsewhere. Finally there does not seem to be any reason why the usual practice of italicising the name of a journal should not be followed.

The number concludes with an Index Medicus, in which all the titles of the papers published during the previous quarter are arranged alphabetically according

to the organ or region with which the paper deals.

The format of the journal is excellent; the size is convenient, and the printing and paper good.

This first number has set a very high standard; if this is maintained, there is every reason to predict a long and successful career.

Current Topics.

Medical Policy in India.

(*Lancet*, March 23, 1929, p. 616.)

It is with mixed feelings that we comment on two addresses, delivered by eminent members of the "independent medical profession" in Calcutta in December last, at a gathering styled the All India Medical Conference. Both Sir Nilratan Sircar and Dr. G. V. Deshmukh, whose addresses have now reached us, as their medical and other distinctions show, have attained a high status in the profession. Their opinions must command a hearing, and the animus displayed in their orations on this occasion is all the more regrettable on that account. What ground exactly the conference in question set out to cover is not apparent, but Sir Nilratan, the chairman of the reception committee, and Dr. Deshmukh, the president of the conference, concerned themselves almost entirely with medical politics in various aspects, and the relations of the independent profession with the Government medical services, and more particularly the Indian Medical Service. It is admitted at once that the work of the medical services, vitally useful as it has been in the development of the country, is open to adverse criticism in certain respects—the sort of criticism which may be levelled at all the European services in India. It is true that in the past the tendency of the official medical men has been to do the responsible work themselves, and to train up their Indian assistants in a subordinate capacity. It is also true that a certain amount of jealousy existed with regard to remunerative appointments and practice, and that vested interests and service claims were sometimes allowed too serious consideration. Then, again, students of the medical colleges and schools had certain real grievances. It has been too much the custom to change professors round from one subject to another, as convenience dictated, without sufficient reference to special qualifications, and teaching has sometimes suffered from this cause. Training in the later years of study and early post-graduate life was likewise adversely affected by the practice of filling house appointments in hospitals by members of the permanent subordinate services, and other handicaps existed which it will take time completely to get rid of. But when eminent Indian physicians say that the British in India have been unprofitable stewards—that Government has done practically nothing for education—that their neglect of irrigation has turned a land of peace and plenty into a home of stark want and fell disease—that the people are decimated by diseases of foreign importation—and that alien authority has only a sneer of indifference for genuine merit—it is unnecessary to deny the charges; we ask what places diatribes of this nature have in a medical conference?

The speakers came to more appropriate subjects when discussing the prospective Bill for the constitution of a central medical council for India, though even here racial bias becomes at once apparent in the terms employed. The proposed legislation, one of the most important objects of which is to put the Indian Empire in a better position to negotiate with other countries, and to maintain and enhance the reputation of its medical degrees in the eyes of the rest of the world, was regarded with quite unreasonable suspicion, and the views of the conference will be widely reflected. It is suggested that the proposals are the sinister product of an alien bureaucracy (although the department directly

responsible for the measure is almost entirely in the hands of distinguished Indians), and that the new central council will be subordinate to the General Medical Council of Great Britain. Hostility to the General Medical Council appears to be a sort of obsession, though people well qualified to know have pointed out over and over again that any intervention by that body in Indian affairs has always been confined to the protection of the interests of the general public at home, while its advice has been of the utmost assistance to India. Do the critics of the Council know what percentage of its work of recent years has dealt with Indian as well as with Colonial affairs? Constantly the President has himself dealt with important Indian matters, while the Council, as a body, has frequently been resorted to for advice on difficult phases of medical policy in India, when applications have always met with a ready and sympathetic response. The suspicious attitude which the spokesmen of the independent profession in India too frequently adopt towards the Council is therefore neither grateful nor well advised, and it is most unfortunate that the same attitude should be adopted with regard to the efforts of the Indian Government to create a body to regulate education, and to meet foreign criticism with regard to the status of the country's medical qualifications abroad. The same distorted and supersensitive nationalism is to be seen in the proposal put forward at the conference with regard to the establishment of chairs in Ayurvedic and Yunani medicine in the medical colleges—this as an extra burden on students who it is contended are already overweighted with a curriculum imposed on them largely through the malevolent machinations of the alien General Medical Council. Persistent ventilation of this matter has always led to the opinion among those who look temperately at the situation that the indigenous systems, however interesting from a historical standpoint, can have no place in a course of study devoted primarily to modern scientific medicine.

It is pleasant to note that Sir Nilratan Sircar ends in a loftier and more reasonable vein by exhorting Indian medical and sanitary experts to devote themselves to investigating various social problems which call for attention; to study the factors which lead to excessive child and maternal mortality, the bearing of defective marriage customs on vitality and fecundity, and the effect of faulty diet and nutrition on various diseases. In these and other similar spheres racial jealousies and ancient differences may surely be disregarded. Meanwhile it is opportune to draw attention to the very liberal reforms which are now in course of introduction in the medical schools and colleges and attached hospitals. A cursory examination of the staffs will show to what an extent the leading educational posts are already held by Indians. Resident hospital appointments are also being increasingly thrown open to the newly qualified non-official men, and, as one of those whose addresses are here under consideration observes with not unnatural satisfaction, most of the lucrative practice of the larger towns has already found its way into Indian hands. These changes, one would think, should go far to meet the aspirations of independent Indian practitioners, and to reconcile them to the retention of what, after all, in relation to the total population of the country, is only an insignificant number of posts in the military and civil medical services, to serve the needs of the rapidly diminishing Europeans in the army and civil services. But apparently nothing short of the total exclusion of Europeans will satisfy these reformers. If no other reason existed against this course, we may remind them that Western science is a plant of comparatively recent growth in the east, and that it would be strange indeed if it were yet ready to flourish alone without external support.

Some Aspects of Dental Sepsis, Focal and Residual.

By TALLENT NUTHALL, M.D. (Lond.).
(*Lancet*, December 22, 1928, p. 1285.)

"A CAREFUL search must be made for any focus of infection, such as a tooth, and, if one is found, it must be eradicated"

A sentence such as this is almost certain to occur in any article or lecture on those diseases which we now regard as the results of bacterial toxæmia. When the teeth are incriminated the focus is believed to be completely eradicated by the extraction of those teeth. Yet it is evident from the results obtained that extractions are by no means a certain cure, and that many patients are no better and some are worse off than they were before. During the last 10 or 20 years so many teeth, innocent and guilty, have been sacrificed that it is coming to be fairly generally held among the lay population that a visit to the doctor is most likely to result in their being advised to part with some or all of their teeth. They see on all sides the dentures, conspicuous or otherwise, of their friends, and note that while some fortunate ones have been cured, many remain crippled. One meets with great divergence of opinion among the profession, and nowadays to mention dealing with the teeth as a cause of focal sepsis is to excite mildly derisive smiles amongst an audience of medical men. There is a general feeling that the thing may have been overdone, that there are factors which are not yet understood. There does seem some reason for believing that the procedure is becoming discredited not only among the lay population but also among the medical profession.

The Teeth in Themselves not the Source of Trouble.—No one will deny that the teeth are very frequently the primary site of the infection, but it is obvious that if the infection is confined to the teeth and the teeth only, generalised symptoms are unlikely to result. A carious tooth is an infected tooth, and many teeth are the subjects of pulpitis, but neither of these conditions will in itself give rise to arthritis or fibrositis. In fact, it is not the infection of one or more teeth that matters. What does matter is the extension of the infective process into the neighbouring structures, first the periodontal membrane and—more important still—the alveolar bone. Both are highly vascular and there are plenty of blood-vessels to carry into the system the toxins which result from bacterial metabolism. Over and above this, the structure of the alveolar process, loose and with a multiplicity of cancellous spaces, is a particularly favourable medium for the growth and spread of organisms. When this invasion takes place the area of infected tissue is enormously and progressively increased, absorption of toxins occurs on the grand scale, and generalised symptoms appear.

How Infection Occurs.—There are three means of infection: (1) via the pulp and root canal; (2) by direct extension from the periodontal membrane; (3) by direct extension from a fragment of root left behind after extraction.

The first commonly results in the formation of an apical granuloma or abscess; that is to say, the process may be localised for variable periods of time. There may, however, be no localisation but an infection spreading into the alveolus without the formation of any line of demarcation such as is necessarily implied by abscess formation. The second is the commonest route. Considering the vast number of teeth which show signs of periodontitis, abscess formation is rare. The process is one of direct extension, first of all in the membrane and thence into the bone.

Every now and then during extraction a fragment of root is broken off and left behind. It is usually already infected, but in any case it becomes so before the socket has healed. After a lapse of time either an abscess forms or else a diffuse infective process starts and spreads in the alveolar bone.

Infection may also occur via the blood stream. It has been suggested that the organisms are carried by the blood stream from some other organ to the teeth, which they apparently select as their site of operation. This seems to be far less frequent than the other routes.

The Role of Pyorrhæa.—Many authorities hold that pyorrhæa is of little or no importance in the causation of arthritis and allied conditions, but the question seems to be entirely one of the extent to which the pyorrhæa has advanced. Strictly speaking, pyorrhæa is a symptom of an infection of the gingiva and superficial alveolus. So long as it is confined to superficial regions from which there is free drainage into the mouth; the effects on the

system are likely to be those produced via the tonsils or the gastro-intestinal tract. Directly, however, the pyorrhoeal pockets involve the periodontal membranes the way is open for direct extension of the infective process in the membrane and thence into the alveolar process.

Dental Skiagrams and their Import.—Apical abscesses, dental cysts, and granulomata are all striking features when seen in dental radiograms. Dead teeth can usually be recognised by changes in the pulp cavity and root canals, which become less defined and may be lost altogether. Periodontitis, when marked, is unmistakable. The healthy periodontal membrane appears in the negative as a fine, clearly defined black line between the tooth and the lamina dura. In periodontitis it is widened, sometimes along the entire surface of the tooth, but more often in parts, so that its outline becomes irregular and uneven. Proliferation of the lamina dura also occurs, so that the periodontal outline may vanish more or less completely, and the shadow of the tooth as a whole loses definition. More important, though less easy to recognise, are the changes which result from infection in the alveolar bone. In a radiogram the cancellous structure of the alveolar process can be clearly seen. The fine trabeculae appear in the negative skiagram as light or white lines, crossing one another at angles and enclosing minute angular spaces which appear darker. When the bone is infected, these appearances change. The details become blurred; in places the trabeculae are thickened and the small angular spaces are replaced here and there by rather larger, rounded spaces which appear almost black. These are minute areas of rarefaction, which are always to be seen in the neighbourhood of the apices of teeth which show periodontitis. They are, in fact, the earliest evidence of the invasion of the alveolar bone by an infective process. Larger oval or irregular-shaped areas of this rarefaction are often to be seen in the interdental septa or just deep to the alveolar margin where absorption is taking place; these denote infection of longer duration. Another common rarefactive change is an irregularly circular or oval area spreading from or around the apex of an infected tooth, an area which is more radioparent than healthy bone and appears greyish in colour or less dense than the surrounding tissue. In it the cancellous structure is less sharply defined and may be unrecognisable. This appearance is caused by a diffuse infection of the alveolar bone, spreading away from an infected apex or root without the formation of a classical abscess or any limiting process. Several such areas may be seen, most often in connection with the premolar teeth. In time they coalesce, and eventually a large part of the alveolar process may be so affected. When the whole or a complete half alveolus is infected the condition is not so easily recognised in the films, but the loss of detailed structure and lack of contrast and density should reveal it. If such an area be explored it will be found spongy and soft, instead of hard and firm like healthy alveolar bone.

Changes in the nature of sclerosis may also be frequently seen. As mentioned above, the lamina dura in the neighbourhood of infected periodontal membrane commonly undergoes proliferation. There may be areas of sclerosis in the interdental septa or adjacent to the apices of the teeth. These areas may replace the whole of the normal alveolar process between two teeth. They appear as almost structureless whitish patches of irregular shape and variable size. By some they are regarded as attempts at repair or defence, but it seems equally reasonable to consider them as early reactive changes evoked by the invading micro-organisms.

The Contribution of Bacteriology.—Although there can be no doubt that a suitable vaccine is one of the most valuable means of treatment, it might be well to ask whether bacteriological investigations can help us in diagnosis. A streptococcus is almost universally held responsible for the lesions we are considering, but it is not possible to incriminate any particular type of streptococcus. It is reasonable to suppose that any streptococcus, given certain opportunities and a suitable environment, is capable of causing disease. The *Streptococcus hemolyticus* and the *Streptococcus viridans*

especially are the two which seem most active in producing arthritis or any infective condition. It is not possible to argue, however, that the finding of a streptococcus in a culture from a pocket or from the apex of an extracted tooth is to be regarded as evidence either that an infective process is at work or that the organism so isolated is causal. Swabs from any structure in the mouth will almost always yield a growth of streptococci of some sort, mixed with other organisms. There are, however, two ways in which bacteriological investigations can help towards forming an opinion. One is when the cultures made from a pocket give a pure growth of a streptococcus, and especially *Streptococcus viridans*, to the exclusion of other organisms. The second is when the patient's serum can be shown to contain agglutinins or other antibodies specific for the organism which has been isolated. Unfortunately, this can only be demonstrated in a small proportion of cases, but when it does occur it may reasonably be argued that infection is taking place and that the organism agglutinated is the offender. The converse argument—that the absence of demonstrable antibody formation denotes a deficient resistance on the part of the patient—cannot be regarded as equally convincing.

The Soil.—The difference in the way in which patients react is a striking feature of these infective conditions. In the imperfect state of our knowledge we explain this as being a question of resistance on the part of the patient. The great prevalence of arthritis, fibrositis, and the other results of focal sepsis seem to point to the conclusion that there is less resistance now among the general population than there was a generation ago. The title given by Fern to his article the *Streptococcus—the Biggest Menace to Mankind*, has a very real application in these days when one considers the very large amount of incapacity and illness caused by his organism. Some patients show a surprisingly high resistance to a degree of infection which would speedily disable others.

Resistance to the results of focal infection is a very variable factor in different people, and one person may carry a focus of infection in his mouth to the end of his life without showing any apparent results from it, while a far lesser degree will speedily disable another. As the resistance varies, so does the recuperative power.

Methods of "Eradication" and Where They Fail.—When it has been decided that infection of the teeth is the cause of a patient's lack of health, the various procedures commonly adopted are:—

- (1) Complete clearance of all the teeth. This may be carried out forthwith without any previous radiographic or other scientific examination, on a "hit or miss" principle which has little to commend it.
- (2) Extraction of the obvious offenders, teeth with granulomata or apical abscesses.
- (3) Extraction of all teeth which show any skiagraphic sign of infection after careful consideration and previous examination.
- (4) Extraction of "dead" teeth only. The number of workers who confine their attentions to dead teeth and strongly oppose the extraction of any tooth which is still vital, whatever may be the radiographic appearances, is a large one, surprisingly large when one considers the inference to be drawn from such limited procedure. This inference is that only dead teeth can be so infected as to give rise to disease. One constantly meets with the expression of this view, not only in this country but also in reports on radiograms made in the United States, and when not expressed it is implied by the fact that only dead teeth have been dealt with. I feel that this opinion is in such strong opposition to the facts that I was greatly tempted to head this paragraph "The Dead Tooth Heresy." Nothing, in the present state of our knowledge, affords any grounds for the supposition that a tooth must be non-vital before it can be concerned in focal sepsis.

Any of these procedures may prove successful. Any of them may fail, and the reason for failure is the same in all the groups. It is because the original treatment is not radical enough and residual infection is left behind. Where a solitary apical abscess, for example, is dealt with by simple extraction, it is reasonable to

expect that the resulting drainage, followed by granulation and healing of the bone, will put an end to the trouble, but when there is diffuse infection involving the apices of two or three teeth or one-half of the alveolar process, then it is not conceivable that the mere extraction of the teeth will in all cases put a stop to the infective process. Most of the softened infected bone is left behind, and in it enormous numbers of organisms continue to multiply and pour their poisons into the blood stream almost as freely as before the teeth were extracted. The gum heals with remarkable rapidity. Even an abscess cavity, left when the tooth has been extracted, is quickly covered over by dense gum tissue before it can be filled with healthy bone. Owing to this rapid healing, the length of time during which drainage can take place is very limited and, where a large area is involved, the amount of drainage must be almost negligible.

The Logical Treatment.—If we are agreed that a certain group of symptoms is due to an infective process, the logical treatment is obviously the removal of the source of that infection. If, in the condition under discussion, we cannot bring about this end by simple extractions, we must take such further steps as will ensure it as far as possible. This means that, in addition to extraction of teeth, any unhealthy bone must be removed also, or, in other words, a partial or complete alveolectomy must be performed. This sounds a formidable undertaking both for the patient and for the operator, but it is not in fact so severe as it sounds. Having submitted many patients to it and from personal experience as well, I can say that the general effects in the way of shock, etc., are slight, the amount of pain little if any more than after ordinary extractions, while healing and consolidation are rapid and dentures can be made to fit quite as perfectly as after simple extractions.

Briefly stated, the operation consists in removing the teeth, elevating a flap of gum tissue, excising the interdental septa, and removing all soft, spongy bone from round the tooth sockets. When hard and healthy bone is reached, the rough edges are smoothed with a burr and the flaps of gum stitched together. Where only a small area of the alveolus is involved it may be possible to remove the unhealthy bone by way of the open socket or by removing quite a small portion of the buccal surface of the alveolus. In any case, the extent of the procedure is determined by the point at which healthy bone is encountered, but the important part of the proceeding is to leave behind no unhealthy bone.

Residual Infection.—We all have patients who have had their teeth extracted without experiencing any improvement of the condition for which the extractions were done. This disappointing result is most common in infective arthritis. It may be that in a certain number the condition of their teeth was not responsible for their trouble, but I believe that many such results are due to residual infection, and this belief is confirmed by radiograms taken of the edentulous jaws. Any or all of the bone changes resulting from infection may be found persisting in the alveolar processes after the extraction of teeth; tooth sockets which have never consolidated and are little more than chronic bone abscesses, areas of sclerosis, and—most frequent of all—areas of rarefaction, large and small, diffuse and limited. If we accept these radiographic appearances as evidence of infection, then we cannot be surprised that the patients do not improve.

There is another type of residual infection which was first described by Eyre. Normally, the occlusal surface of the alveolar process appears in the radiograms as a sharply defined, smooth edge when consolidation is complete after the extraction of the teeth. One frequently sees small areas where the smooth edge is replaced by a number of minute irregular, bony projections resembling the teeth of a fret-saw. These areas are due to persistent infection deep to the gum, and Eyre has demonstrated the invariable presence of the *Streptococcus viridans* in cultures made from these bony spicules. Such a state of affairs is clearly capable of maintaining a supply of bacterial toxins in the general circulation.

Alveolectomy versus Extractions.—This does not mean that we should advise alveolectomy, partial or complete, for every patient who is suffering from the effects of focal sepsis arising in connection with the teeth. We know that in a large number of cases simple extraction of the infected teeth is sufficient to bring about cessation of the trouble. Patients vary in their resistance and in their recuperative power.

In one patient the extraction of teeth and the short period of drainage which follows is sufficient to swing down the balance towards a recovery which may be permanent. In others a temporary improvement is followed by the gradual reappearance of their troubles. It is difficult to tell beforehand how any one particular patient will respond to extractions, and there are a certain number in whom it is difficult to decide whether alveolectomy is called for or whether simple extractions will prove sufficient. We may divide all patients into three classes. In the first come patients with one or perhaps two apical abscesses or a granuloma, in whom the process is limited, and whose general condition is good. For these it may reasonably be expected that simple extractions are all that is required. Class 3 consists of those who have an obvious diffuse infection of one or both alveolar processes and who show signs of a severe degree of toxæmia in addition to joint or fibrositic trouble. These call for alveolectomy. In this third class also come the patients whose alveolar processes show residual infection after their teeth have been extracted. Class 2 is the one which affords considerable difficulty. There may or may not be a granuloma, but two or three teeth show a considerable degree of periodontitis with early changes in the bone. Possibly the premolars show periodontitis, while the molars show loss of definition of their apices and of the surrounding alveolar bone. I believe that all such cases should have the position laid clearly before them and be advised to have alveolectomy performed, especially when there is any degree of toxæmia. These are the patients who are likely to improve with simple extractions, but after a time they will relapse and slowly become worse than before, because infected bone has been left behind.

Clinical Condition of Patient the Deciding Factor.—The interpretation of dental radiograms is a matter of considerable difficulty, and the difficulty lies, not in deciding which teeth are diseased, but in determining which are healthy. In practically every set of dental radiograms there are appearances which can be interpreted as evidence of disease. For instance, there are few people who do not show some degree of periodontitis, especially round their premolar teeth. Hence it is not possible to decide from the radiographic appearances alone what procedure must be undertaken to bring about the cure of any case. Just as it is the general clinical examination which in the first instance brings the teeth under suspicion, so the final decision can only be made on the results of this examination. The signs and symptoms must be evaluated and an attempt made to determine the degree of resistance and recuperative power, especially taking into consideration the amount of lassitude, tiredness, and mental depression. The blood must be examined to find out the degree of anæmia and the proportion of polymorphonuclear leucocytes to lymphocytes. Bacteriological and serological examinations should be made. These results are collated, and in the light of this knowledge the radiograms are examined in order that the final decision can be made as to the extent of the mischief and the procedure required to eradicate it. This decision must ensure, first, that no innocent teeth are sacrificed; and secondly, that no infected tissue is left behind to continue the disease. Whatever course is decided upon, vaccine therapy will be required after the mouth has been dealt with. Finally, an immunising course of vaccine administration must always precede any operative measures, for there are a number of cases on record in which fatal septicæmia or septic pneumonia has followed the extraction of a number of infected teeth. It is, moreover, a matter of regrettably common experience to meet with patients in whom an infective process, involving only one or two joints, has flared up and affected many or all of the

remaining joints because they had not previously been protected by an immunising course. In arthritis and the allied conditions we are dealing with some of the most prevalent and crippling diseases which afflict mankind, and our measures, both diagnostic and curative, must be commensurate.

The Treatment of Burns and Scalds by Tannic Acid.

By G. HERZFELD, M.D., F.R.C.S.E.

(*The Practitioner*, February, 1929, Vol. CXXII, p. 106.)

In considering the treatment of burns and scalds, one aims at the following:—

(1) Prevention of absorption from the injured tissues.

(2) Prevention of local sepsis.

(3) Painless dressing or covering for the burned area.

(4) Rapid healing with a minimum of scar formation.

In tannic acid we have, I believe, the ideal substance for the attainment of these aims. Its action when applied to the denuded surface of the body is as follows:—

(1) The tannic acid produces a local coagulum over the raw surface and thereby renders the products of the burn insoluble, so that no absorption takes place into the general circulation.

(2) By the formation of a practically waterproof and rigid covering over the denuded surface, little or no local sepsis is likely to occur in the majority of cases.

(3) The actual application of the tannic acid is painless and pain-relieving, and no further dressings are required once the formation of the coagulum is complete.

(4) As a result of the coagulum formation, healing progresses undisturbed beneath the covering thus formed, and the injury to the granulations so often caused by changing dressings is avoided, with the result that healing takes place rapidly. In second degree burns, it has invariably been found that the scar left is superior to that produced by other methods, and no contractures are caused.

Method of Application.—For the purpose of treating burns and scalds, we have used a 2.5 per cent. solution of tannic acid in sterile water, as first advocated by Davidson, but we have gradually modified his actual methods and have entirely given up the use of tannic acid ointment, which he advised for application to the face. The solution of tannic acid *must* be freshly prepared for every application, for tannic acid left in solution is rapidly converted into gallic acid. The simplest method of obtaining a solution of the correct strength is to keep the powder in packages of 110 grains, to be dissolved in a half-pint of water.

In dealing with an individual case the patient must, of course, be treated according to the extent and severity of the burn. When shock is present, this must first be combated by the application of warmth and fluids, and, if necessary, the administration of morphia. It is, however, important to treat the local condition as soon as possible, in order to prevent absorption of toxins. The burned parts should be cleansed with methylated spirit, all blisters should be opened and the overlying epithelium removed, and a final cleansing with ether to dry the parts is advisable. The tannic acid is now applied with an ordinary spray, the whole affected area being treated. Tannic acid has no effect on healthy skin, so that no fear need be entertained of applying too much.

It may sometimes be advisable to administer a general anæsthetic for the preliminary cleansing and application, but we prefer to do without, though a light gas and oxygen anæsthesia is unlikely to do much harm. The patient is now covered with a cage, into which an electric bulb is placed, so that the burned areas are left uncovered, while at the same time body warmth is maintained. The tannic acid is reapplied in the same manner every hour until the coagulum shows definite signs of forming. The coagulum at first is yellowish and gradually deepens, until after five to eight

applications a warm brown colour appears, which varies in depth at different sites. Thereafter no further application is required, but the coagulum will continue to deepen until it is practically black. During this time if necessary morphia is repeated and fluids should be forced by the mouth, rectum and skin. Where the face is burned, the eyes, nose and mouth must be protected from the action of the tannic acid. In those cases where it is impossible to avoid pressure on the affected parts, as, for instance, when both front and back are burned, the tannic acid is applied with a spray, after which a light sterile dressing is applied to those parts which cannot be left exposed. When necessary, and fairly frequently in young children, the limbs will have to be secured by means of a clove-hitch to the sides of the bed, in order to prevent damage to the coagulum.

Once the coagulum has formed nothing further is required in the way of dressings, though occasionally further blisters may form and have to be snipped and treated similarly. The coagulum becomes dry and leathery and deepens in colour day by day.

Application of the tannic acid is painless, and as soon as coagulation occurs all pain is relieved and the patient becomes quiet and restful. In a case which is progressing well, no further treatment is required excepting that the bed-clothes must be carefully kept off the burned area, as the coagulum should not be disturbed until it begins to separate of its own accord, about the seventh to the tenth day.

It is very important that even when sepsis supervenes, no wet dressings should be applied on the top of the coagulum. Davidson pointed out that the application of moisture almost invariably leads to a rise in temperature and symptoms of toxæmia, and this has been our experience also. Should sepsis occur the coagulum must be completely removed before any form of moist dressing is used.

When the coagulum separates it will be found, in the case of second degree burns, that healing is almost complete. The small superficial raw areas occasionally left can be treated by any simple antiseptic ointment.

The most striking result of this treatment is the fact that in the majority of cases the stage of toxæmia is entirely absent, or at most so slight as to give rise to no anxiety. Where formerly the temperature often rose to 103° or 104° on the third day, and the patient was obviously dangerously ill often for many days, we now find that as a rule the patient's temperature does not rise above 99° or 100°, and the general condition remains throughout most satisfactory, even where an extensive superficial burn is present. It is indeed amazing to note how slight the general reaction is, compared with cases in which other methods have been used. In many cases one has no anxiety about the patient after the first twenty-four hours, and the patient himself is comfortable and placid.

To summarize the advantages of this method of treatment, one may state with confidence that it is quite the most satisfactory line of treatment yet tried:—

(1) The drug is easily prepared, provided the tannic acid powder is kept at hand.

(2) Its application is simple and painless, and pain is quickly relieved.

(3) The result of the formation of the coagulum is, first, to prevent absorption of toxins; secondly, to lessen the loss of fluid from the raw surface; and thirdly, dressings can entirely be dispensed with.

(4) Healing takes place more rapidly than with any other method, with the result that the patient is kept a relatively short time in hospital. In our experience most patients are discharged in ten to eighteen days.

(5) The scar formation with this method is most satisfactory and rapid. We have not had to skin-graft a single superficial burn since using this method.

(6) Nursing is greatly simplified, provided the child is in hospital or a nursing home. The patient is comfortable throughout and rarely becomes either restless or irritable.

(7) The case mortality, at any rate in children, has improved enormously. In my own experience the percentage mortality has dropped from 38 per cent. to 9 per

cent. This point alone would justify the use of tannic acid.

The only disadvantage of this method is that the patients require skilled nursing, in order to ensure that nothing in the way of bed-clothes, etc., touches the coagulum. Patients must invariably be admitted to hospital or a nursing home, and cannot be treated as out-patients.

It must be noted that this method is rarely applicable to cases of burns and scalds which have been treated previously for longer than twelve hours by any other method, and once toxæmia through absorption has occurred, tannic acid is powerless to help. Moreover, no coagulum will form after about 24 to 36 hours, so that in order to get the best result in these cases burns should immediately be treated by tannic acid.

The Value of Modern Tests in Renal Disease.

By G. E. BEAUMONT, M.A., M.D., F.R.C.P., D.P.H.

(Practitioner, January, 1929, p. 28.)

THE failure in a number of cases to correlate the pathological condition with the clinical picture makes it seem advisable that for clinical purposes a purely clinical classification should be adopted:—

(1) *Acute Nephritis*.—Three types may here be distinguished, according to the mode of onset of the disease. (a) *The hemorrhagic type*: This was comparatively frequent during the Great War, and is met with in civil practice from time to time, especially in children. The first symptom noted is that the urine is very dark, and on examination it is found to contain blood, usually in large quantities. (b) *The toxæmic type*: Here the patient complains of various symptoms, such as headache, nausea, dyspnoea, pain in the back, and perhaps vomiting and diarrhoea. An initial soreness of throat may have occurred. (c) *The exudative type*: The patient notices that he is swelling, either in the legs, face, body, arms, or generally.

(2) *Chronic Nephritis with Œdema*.—(Hydræmic Nephritis.) In this group we include subacute nephritis, in which there is usually a history of acute nephritis, the patient now showing œdema with albuminuria. It also comprises chronic parenchymatous nephritis, lipoid atrophy, and such varieties of nephritis whose names are based on their morbid anatomy, as large white kidney, the red kidney, large mottled kidney and small white kidney, or secondarily contracted kidney. Lipoid atrophy is introduced to imply a condition of generalism associated with renal degeneration. It is thought to be synonymous with chronic parenchymatous nephritis. Clinically, there is a history of onset, in a young patient. The œdema is severe, and the basal metabolic rate is low. Characteristics of the blood and urine are

(3) *Nephritis with slight or no Œdema*.—(Chronic Nephritis.) Included in this group are all nephritis, known also as small red kidney, gouty kidney, arterio-sclerotic kidney, senile or atheromatous kidney, and also cardiovascular changes and hypertrophy, arterio-sclerosis.

of 2 and 3.—A with show considerable in the

In chronic nephritis there is a tendency for the night volume to increase. The specific gravity of the day and night specimens should also be determined. Normally it is about 1.018 by day and 1.026 by night. In chronic nephritis there is a tendency for the specific gravity to fall, and "fixation" may occur, so that the specific gravity does not rise at night. Protein should be tested for in the day and night specimens, and the urine may be sent to a laboratory for the determination of the relative amounts of albumin and globulin. If albumin is present in the day specimen and absent from the night one it is suggestive of a functional albuminuria. In nephritis there may be 6 parts of albumin to 1 part of globulin whereas in functional proteinuria only 1 part of albumin may be found to every 2 parts of globulin. The urine should also be examined microscopically for casts, cells, crystals and organisms. In this way an albuminuria resulting from a mild degree of cystitis would not immediately be diagnosed as due to nephritis. The presence of organisms with bladder epithelial cells and pus cells, and the absence of casts and renal epithelial cells, would give the clue to the diagnosis.

(2) *Examination of the Blood*.—This can easily be carried out in general practice if the patient is willing to submit to vein puncture. It should always be urged, as very important results are obtainable. Six to eight cubic centimetres of blood are withdrawn from a vein in the arm with a needle and syringe, and the blood is immediately placed in a small glass tube containing a pinch of potassium oxalate crystals to prevent clotting. The specimen is then sent to the laboratory for analysis. The normal figures are as follows:—

Urea	..	20—40	mgs. per 100 c.cm.
Non-protein nitrogen	..	20—40	" " " "
Creatinin	..	1—1.5	" " " "
Uric acid	..	2—3.5	" " " "
Cholesterol	..	150	" " " "
Chlorides	..	500	" " " "

In hydræmic nephritis there is usually an increase in the blood chlorides or cholesterol. In azotæmic nephritis an increase occurs in the urea, non-protein nitrogen, creatinin and uric acid. In acute nephritis there is often nitrogen retention in the early stages.

(3) *Elimination of Natural Substances*. (a) *Water*: The patient empties his bladder first thing in the morning and then drinks a pint of water. Nothing more is taken by mouth until the test is completed. The urine is collected every hour for three hours. In health, a pint of urine should be evacuated in this time, but in nephritis the amount may be reduced. (b) *Urea*: This test is performed for the water test, but after emptying the bladder the patient drinks 15 grams of urea dissolved in about 30 ozs. of water and flavoured with orange. The urine is passed at the end of one and of two hours, and sent to the laboratory to be measured and have the urea content determined. Normally, the first-hour specimen contains 1.5 per cent., and the second over 2 per cent. of urea. With deficient renal function lower figures may be obtained. Diuresis produced by the urea often accounts for the low figure in the first specimen.

(4) *Excretion of Dyes*.—These tests are chiefly of value in surgical cases in which the function of each kidney has to be determined separately. 0.1 gram of indigo carmine is injected intramuscularly after cystoscopy, and the dye should be seen exuding from the orifice of each ureter in about six minutes. If there is deficient renal function on either side, there is delay in elimination of the dye.

The Clinical Value of Renal Function Tests.

We can now profitably consider the clinical value of the renal function tests described. There is no doubt that great help is obtainable in many cases in the following ways:—

(1) *Determination of the Type of Nephritis*. (a) *Acute nephritis*. The urine: The volume is reduced, but its specific gravity is increased. There is abundant protein; hyaline, blood or epithelial casts may be found, with red and white blood corpuscles. *Blood chemistry*: The urea and non-protein nitrogen figures

are usually raised during the early stages. (b) *Hydræmic nephritis*. In *subacute nephritis*. The urine: The volume is reduced, specific gravity raised, protein is moderate or abundant, and there are usually some granular casts and red corpuscles present. *Blood chemistry*: There may be some nitrogen retention, but usually the cholesterol is normal. In *chronic parenchymatous nephritis* or *lipoid nephrosis*. The urine: The volume is diminished, specific gravity raised, and protein occurs in fair quantities. There are some casts, fatty, hyaline or epithelial, and some leucocytes, but no red corpuscles. *Blood chemistry*: The cholesterol is increased to 300 or 500 mgs. per 100 c.cm. The chlorides may be slightly increased. The blood nitrogen is not usually raised except in the terminal stages of the disease. (c) *Azotæmic nephritis*. The urine: the volume is increased, especially by night. The specific gravity is low by day and night. The protein is scanty and occasional hyaline casts may be found. *Blood chemistry*: The urea, non-protein nitrogen and creatinin may be raised. The chlorides and cholesterol are usually normal. (d) *Mixed types*. The urine: Protein is found in moderate amounts, and a few granular or epithelial casts may be present. *Blood chemistry*: There may be retention of nitrogen and also of chlorides and cholesterol.

(2) *Determination of the Severity of the Nephritis*. The urine: Large amounts of protein, up to 10 per cent., usually indicate severe and acute nephritis. Protein present only in the day specimens, or after strenuous exercise, suggests a functional condition. A relative increase of globulin is also indicative of functional proteinuria. Blood usually points to acute or subacute nephritis. *Blood chemistry*: The nitrogen is said not to rise unless three-quarters of the total renal tissue is damaged. The severity of the nephritis is roughly proportional to the blood urea and non-protein nitrogen figures, provided that other causes of nitrogen retention are excluded, such as urinary or intestinal obstruction. Thus, an enlarged prostate interfering with complete evacuation of the bladder will cause nitrogen retention in the blood. The severity of a lipoid nephrosis is probably roughly proportional to the degree of cholesterol retention. *Urea concentration test*: Low figures are usually found when there is much renal damage. There is, however, a fallacy in the test, as the rate of urea absorption depends upon the speed at which the stomach empties. Thus a variable factor is introduced.

(3) *Determination of the Prognosis in Nephritis*. *Blood chemistry*: If the blood urea figure is over 400 mgs. per 100 c.cm., death is almost inevitable in a short time. With a figure of 300, the patient may live for a considerable while. If the creatinin is above 7 mgs. per 100 c.cm., the case may be regarded as hopeless.

(4) *Determination of and Control of Treatment in Nephritis*.—As renal function tests materially assist in the diagnosis of the type of nephritis, they also indicate the kind of treatment required in any case.

In *acute nephritis* the patient should be given moderate fluid and low protein diet. The ordinary "milk" diet should be avoided, and a diet given consisting of milk 2 pints, egg 1, rice (dry) 3 ozs., and bread 10 ozs. This contains 70 grams of protein, which are practically sufficient for an adult on an ordinary diet, in health. The following diet may be given: *Days 1—3*. The total fluid should not exceed 3 pints in 24 hours. Water, barley water, imperial drink, and glucose orangeade (8 ozs. glucose in $\frac{1}{2}$ pint water, flavoured with the juice of an orange) may be given, but no solid food. *Days 4—5*. After diuresis has occurred, or when the blood in the urine has lessened, the diet may be increased as follows: milk $\frac{1}{2}$ to 1 pint, glucose orangeade 2 pints, a little coffee, thin bread and butter, Benger's food cream $\frac{1}{2}$ oz., sugar and weak tea. *After 7 days*. Two pints of milk may now be given, with bread and milk, sugar, toast, bread and butter, honey, cream and potatoes. Later can be added milk pudding, suet pudding, porridge, bananas, steamed fish, chicken, boiled lamb and one egg a week.

In *Hydræmic Nephritis*. (a) In *subacute nephritis*, in which there is persistent oedema, a salt-free diet may

be tried. The Karrell diet is as follows: *Days 1—7*. Milk 8 ozs. at 8 a.m., 12 noon, 4 p.m. and 8 p.m. *Day 8*. Add at 10 a.m., one lightly hoiled egg and a slice of toast. *Day 9*. Add 2 ozs. vegetables as asparagus, celery, cauliflower or carrots, and 2 teaspoonfuls of starch to the mid-day milk feed to form a vegetable soup. Give also one slice of toast at 4-30 p.m. *Days 10—12*. Add 1 egg and 1 oz. rice, weighed dry. (b) In *lipoid nephrosis* an Epstein high-protein-and-low-fat diet may be given. This should contain protein 120—240 grams, carbohydrate 150—300 grams and fat 20—40 grams. The total fluid should be between 40 and 50 ozs.

In addition, thyroid extract should be given in large doses (15 or 20 grains daily) as long as the blood cholesterol remains raised. If the blood analysis shows there is marked nitrogen as well as cholesterol retention, then the high protein diet is contra-indicated.

(c) In *azotæmic nephritis*, a moderate nitrogen diet is required, containing about $\frac{1}{3}$ gram of protein per 1 pound of body weight, which is equivalent to 70 grams of protein for a man weighing 10 stones.

Testicular Pain.

By KENNETH WALKER, O.B.E., M.A., M.B., F.R.C.S.
(*Proctitioner*, January, 1929, p. 56.)

THE testicle and the vas are well supplied with nerves coming from an extensive base, the renal, the aortic and the hypogastric plexus. The nerves derived from these sources anastomose freely, and as a consequence the testicle is frequently the site of pain referred from other organs, notably the kidney. But there is another fact besides this liability to be the seat of referred pain that renders the study of testicular discomfort important. There is no organ in the body more liable to be the centre around which a neurosis is formed than the testicle of a man or the ovary of a woman. The importance of ovarian pain in this connection is fully recognized, but much less has been written on the subject of the painful testicle. For this reason no apology need be offered for dealing with a condition that is not only of great importance to the patient concerned, but also one that is not infrequently met with in general medical practice.

For the sake of convenience cases of testicular pain may be divided into two groups: those in which the cause of the pain lies outside the genital tract (for example, in the kidney), and those in which it is due to local lesions. Of referred testicular pain little need be said; its significance as a symptom of renal colic, or of lesions in the neighbourhood of the renal and aortic plexus is readily appreciated. Of greater importance from the point of view of this article is pain due to organic lesions of the testicle itself. Here inflammatory conditions take first place. In cases of acute epididymitis the pain may be intense and the testicle so exquisitely tender that the slightest pressure may cause the patient agony. The pain is often a nauseating variety and the patient may actually vomit. When on the right side the symptoms may suggest appendicitis, owing to the fact that the cord is also tender and the abdominal wall over the iliac fossa rigid.

With rest and hot applications some relief is afforded, but when such methods are insufficient, ease is obtained by resorting to puncture of the swollen epididymis. This must be done with care. A large-size hypodermic needle is selected and the point driven into the swollen globus minor. From it a small amount of blood-stained fluid is aspirated by means of a syringe. Some authorities recommend that after aspiration $\frac{1}{2}$ to 2 c.cm. of electragol be injected into the tissues but this is not to be recommended as a routine measure. For puncture Hagner substitutes open incision, if necessary, under local anaesthesia. The incision is carried down to the tunica vaginalis testis and the epididymis punctured in five or six places with tenotomy knife. After washing out the tissues with saline the layers of serotum are closed with two lines of sutures, drainage being provided for by means of a rubber dam. It might be thought that either of the above proceedings would be liable to leave the

epididymal canal permanently damaged and the patient sterile. Actually it has been found that sterility was less frequent in a series of cases of epididymitis treated by puncture or incision than in a control series treated in the ordinary way.

As a contrast to the intense pain of acute orchitis is the dull ache that is associated with such lesions as chronic epididymitis, varicoceles, hydroceles, cysts and new growths. Here the discomfort is likely to be intermittent, or at any rate to vary in its intensity. No relation exists between the size of the lesion and the severity of the pain. Indeed, in the case of varicocele, more discomfort is often complained of when the varicocele is small than when it is large. In writing of this condition, Quenic states that phlebitis and neuritis are frequent complications, the former accounting for the intense pain sometimes felt with varicocele, and the latter for the atrophy of the testicle that may follow it. What is certain is that the severity of the pain in varicocele depends on the state of vascularity of the genital tract. It is always aggravated by ungratified sexual stimulation and relieved by normal coitus. Constipation and a sedentary life tend to increase it, moderate exercise and regular action of the bowels to diminish it. Usually the symptoms of varicocele are most pronounced in psychopathic individuals introspective in character, and easily fatigued. Once his attention has been drawn to his genitalia a man of this type soon becomes hypersensitive of changes in sensation in that portion of his anatomy. He takes to examining himself in order to discover any abnormality, and before long he discovers not one, but many. Some chance remark by an ignorant friend on the subject of loss of virility throws him into despondency, and in a short time he becomes a sexual neurasthenic.

It is this tendency of the patient with a varicocele to develop a neurosis that makes the condition a difficult one to treat. An operation more often than not makes matters worse. If the end results of all operations for varicocele were collected and analysed, it would be found that the operation is neither as successful nor as free from complications as is generally supposed. Ligation of the pampiniform plexus almost inevitably leads to profound changes in the testicle. E. M. Corner and C. A. R. Nitch published the remote results of 100 operations for varicocele and found that in 90 per cent. hardening of the testis due to fibrosis had occurred. In 23 per cent. a hydrocele had appeared on the site of the operation. Both the fibrosis and the hydrocele were the result of venous congestion following ligation. It must, of course, be admitted that varicocele itself, quite apart from its operative treatment, may be associated with changes in the testicle in the way of fibrosis. More especially is this likely in those cases in which phlebitis and thrombosis are present as complications, but even allowing for this it is certain that operation hastens rather than retards the appearance of degenerative changes in the testicle. Hardening of the testicle and the development of a hydrocele can scarcely be considered in themselves serious complications. But to a patient who has become neurotic over his varicocele, their appearance spells disaster. He has submitted himself to an operation only to jump from the frying pan into the fire. Moreover, if the cause of his pain lay in a neuritis of the nerves of the cord rather than in the varicocele itself, his testicular discomfort may be worse even than it was before. Such patients become an embarrassment to their doctors and a trial to their friends: operations not only fail to relieve the symptoms, but may even aggravate them. Corner and Nitch, in their paper on the remote results of operation, state that 70 per cent. were relieved of their symptoms and only some 4 per cent. rendered worse. The writer's experience of after-results has been less favourable. There are many patients who, although they may ultimately lose their pains, pass through a period of increased discomfort immediately subsequent to ligation, and as a result not a few of these become definitely neurotic. The fact that varicoceles appear at puberty and disappear in old age suggests that they are dependent on sexual activity. An additional proof that this is so is furnished by the

observations that they disappear when the testicle atrophies, as, for example, after the orchitis of mumps. Varicocele *per se* is not a cause of pain, and more often than not its owner is not aware of its existence. It is only when the genitalia become congested, especially as the result of ungratified sexual excitement that the varicocele causes discomfort. The postponement of the marriage age in civilized lands has probably had more effect than any other factor in producing painful varicoceles. J. B. Barney, in an analysis of 403 cases of varicocele, found that 81 per cent. occurred in youths and unmarried men below the age of 35.

The lesson to be drawn from this is that in treatment operative measures should be regarded as a last resort. Every effort must be made to relieve pain by diminishing congestion, and special steps should be taken to guard against the danger of the condition becoming the starting point of a neurosis. The ideal treatment would lie in marriage, but as this can scarcely be regarded as a therapeutic measure, the use of a good suspensory bandage must be prescribed. Many of these are ineffective. The best form of bandage is that worn by jockeys and hunting men and known as a "jock strap." This consists of a broad strap attached to an elastic belt which carries the whole of the external genitalia upwards and forwards over the front of the pubis. Not only does it lift the testicles but it exercises a certain amount of pressure on them. Additional measures consist of careful regulation of the bowels, the avoidance of standing and of sexual excitement, and the use of morning applications of cold water to the skin covering the varicocele, followed by bending exercises. If the vesicles on rectal palpation are tender, emptying by massage should be added to these measures.

Of equal importance is the psychological treatment of the patient. He should be told that a certain degree of varicocele is so common as to be the rule rather than the exception. He must next be assured that the worst effect it can have is to occasion a certain amount of aching and that it cannot cause impotence or atrophy of the testicles. He can be told that with increase of age, and especially if he marries, the condition will disappear of itself.

Only if this treatment fails, or if the symptoms local to the varicocele far outweigh the general and neurasthenic ones, need the question of operation be considered. To operate on a case in which neurasthenia has already developed is to court disaster. Patient and surgeon alike will come to regret the day on which the operation was performed.

Reviews.

PROTOZOLOGY, A MANUAL FOR MEDICAL MEN.—By John Gordon Thomson, M.A., M.B., Ch.B. and Andrew Robertson, M.B., Ch.B. London: Baillière, Tindall & Cox. 1929. Pp. XVI plus 376, with 4 colour plates and 220 figures in the text. Price 30s. net.

RECENT years have seen the publication of one after another textbook on medical protozoology, and it is clear that teachers of this subject have one and all realised the necessity for handbooks for post-graduate students and laboratory workers in it. Thus there have been published in succession Hegner and Taliaferro's *Human Protozoology* (1924), the textbook at the Johns Hopkins University; Craig's *Parasitic Protozoa of Man* (1926), the textbook for the U. S. A. Army Medical School; Knowles' *Introduction to Medical Protozoology* (December, 1927), the textbook for students at the Calcutta School of Tropical Medicine; and now, finally, the book under review, intended as a textbook for students at the London School of Tropical Medicine. We must also add Wenyon's splendid *Protozoology, a manual for medical men, veterinarians and zoologists* (1926), which is a complete and comprehensive library manual

rather than a book for students. Thus, whereas a few years ago the student had no textbook, now he has a wealth of books from which to choose.

On reading through this book, four facts strike one at once. The first is the most admirable standard of publication achieved. We are accustomed to sumptuous textbooks issued by American publishers, lavishly illustrated and got up, but this work, issued by British publishers, is perhaps ahead of anything issued in America. It is printed throughout on thick glazed paper, well bound, of convenient size, and the students at the London School of Tropical Medicine are to be congratulated on so admirably got up a textbook.

Secondly, the authors have devoted considerable sections of the book to the pathology of protozoal diseases, since they consider that medical protozoology cannot be taught without a study of the pathological reactions of the tissues to protozoal infections. In this matter, we consider that they are right; and the inclusion of these sections lends an added value to the book.

Thirdly, the illustrations are splendid. The colour plates are in every way admirable, and have been admirably reproduced. A most noteworthy feature of the book is the inclusion of very many photomicrographs. These constitute a simply splendid series, and will be of the utmost interest to laboratory workers everywhere. In this matter the authors have followed the lead given by Craig—and, incidentally, gone one better.

Fourthly, the size of the book calls for comment. It is exceedingly difficult for a teacher to get inside the mind of his students, as it were, and to judge their requirements: to know what to include and what to exclude. In discussing this point with a very experienced professor, the latter remarked to the reviewer, "Pick out the man whom you consider to be the stupidest in the class, and try to talk down to his level of understanding." Personally, the reviewer has never taken this advice or followed this plan; he considers that post-graduate students should be given the very best that the professor can provide, in the hope that the stupid student will pick up the minimum essentials of the subject, but that the capable and conscientious student—who will become the medical research worker of the future—will gain a real grasp of the subject, become interested in it, and prosecute enquiry into it on his own initiative in future years.

Thus it becomes very difficult for a professor to know what to include and what to exclude. In this respect the present volume strikes the happy mean. It is essentially a post-graduate student's book. It includes complete sections on the spirochaetes, the *Rickettsia* and other intracellular bodies, *Sarcocystis* infection, such fungi as *Rhinosporidium* and *Cryptococcus*, and a chapter on technique. It is thus at once comprehensive and compact, which is what is wanted in a student's manual.

Having said so much by way of general remarks about the book, let us now attempt to deal with it in more detail. The authors prefer to adhere to the definition of the protozoa as unicellular rather than as non-cellular animals. They adopt the universally accepted classification, after Doflein and Wenyon, but introduce the classes of the Sporozoa in a different order to that usually presented, beginning with the Coccidiomorpha and the malaria parasites—as being the most important cause of disease in the tropics, and not dealing with the entamoebæ of man until Chapter XXI. This arrangement may have its merits; it certainly at once introduces the student to the study of malaria, the most important disease of the tropics. In the reviewer's experience, however, the subject which the student finds it most difficult to grasp is the identification of the human entamoebæ, and he himself is accustomed to commence with the Rhizopoda, and to keep his students at the identification of intestinal protozoa in stools throughout their six months' training—introducing the study of the malaria

parasites at a later date. The matter is one, however, on which a difference of opinion may well exist.

The book is in a way very complete, and nothing essential has been omitted. Yet the reviewer feels that it is a book which is very difficult to review, because a reading of it leaves him with a sense of its incompleteness. In this matter he is probably prejudiced; and the post-graduate student will probably find all that he requires in the volume. In brief, the book may very well—(probably does very well)—serve as an introduction to medical protozoology; yet it leaves the serious student of the subject unsatisfied. The sections on the parasitic protozoa are so good that one wishes they were a little more complete; and the same remark applies to the excellent sections on pathology.

In one matter the reviewer hopes that the authors will forgive him from completely disagreeing with them. On pp. 362 to 365 the authors give a list of only 48 references to the literature, and in their preface they explain that no attempt at an exhaustive catalogue of references has been made. In a students' textbook this attitude is possibly right—the student (except the more interested one) may not require references, but the laboratory worker, and especially the man who is preparing papers for publication, does require such references, and in this point the latter class of worker will find the book disappointing. Again, however, from the student's point of view, the authors are possibly right. On the other hand, on pp. 357 to 362 the authors give an exceedingly valuable list of derivations and definitions; this is one of the most admirable features of the book; it will appeal alike to students and laboratory workers, and is most useful.

Plate III, fig. 24, has especially interested the reviewer. It depicts a polymorphonuclear leucocyte simply crammed full of merozoites of *P. falciparum*, also with hemozoin pigment. The reviewer confesses that this illustration intrigues him greatly, because in more than twenty years' study of malaria, off and on, he has never seen a similar phenomenon. Presumably malarial merozoites are phagocytosed by the polymorphonuclear leucocytes, but it is curious how very seldom this phenomenon is encountered, even in blood films showing an intensive infection.

One cannot write a textbook without making mistakes, and the reviewer hopes that the authors will forgive him for pointing out two mistakes in their account of the transmission of Indian kala-azar. In doing so, he pleads guilty to making several similar mistakes himself.* On p. 218 the authors write as follows: "A considerable amount of credit is due to Sinton (1922), who first pointed out to the workers in Calcutta that the distribution of kala-azar corresponded almost exactly with the geographical distribution of the sand fly, *Phlebotomus argentipes*." This might lead some future worker on the subject to search for "Sinton (1922)"—a paper which does not exist. The true facts are that it was Grassi in 1907, in a paper on the taxonomy of sandflies, who first drew attention to a statement by the traveller Pressat in 1905 that "flies"—i.e., sandflies—were considered to be the transmitting vectors of *L. tropica* among the inhabitants of Tashkent. This statement appears to have been copied into Laveran's *Les Leishmanioses* (1917) without acknowledgment to Grassi. Acton's paper in 1919 drew attention to the identical distribution of oriental sores and of sandfly bites on the body, and from 1921 to the present date Lieutenant-Colonel H. W. Acton, I.M.S., has always been the inspirer of the work in Calcutta on *P. argentipes* with regard to the transmission of kala-azar. A reference to Knowles' *Introduction to Medical Protozoology*,

* Especially in his *Introduction to Medical Protozoology*, in stating that Dobell states that *Entamoeba histolytica* never produces all octonucleate cyst. This is entirely erroneous. Dobell did not make such a statement, and his paper in *Parasitology* for December, 1928, very clearly depicts such octonucleate cysts.

p. 232, gives the true facts: that, believing that sandflies are the vectors of *L. donovani* (in India), the reviewer wrote to Colonel Sinton in 1923 asking him for information, and Colonel Sinton replied that the distribution of *P. argentipes* appeared to correspond with that of kala-azar in India. The enquiry at Calcutta owes the greatest debt to Colonel Sinton for his invaluable help and assistance, but he did not publish a paper in 1922 on the subject, though he referred to it in a paper published in 1925.

A further inaccuracy with regard to the work at Calcutta is that "Knowles, Napier and Smith (1924) fed sandflies on a kala-azar case, and ten out of eleven females showed the midgut infected with leptomonads on the third to the fifth day. (All flies used as controls were negative.)" The facts are that the development of *L. donovani* into its herpetomonad form in *P. argentipes* was observed by these workers in ten out of eleven consecutive feeding experiments undertaken during the monsoon period of 1924; (25 out of 56 fed flies positive, with 857 negative controls).

The reviewer desires to point out these two—very minor—errors, not with a desire to criticise this most valuable book, but with a desire to get the true facts correctly recorded in the literature, since a mistake which gets into one textbook is generally copied into others. The facts, as presented by the authors, are in the main correct, but these details are wrong.

These, however, are almost insignificant points. In the main this book is a most admirable one, and in every way will serve the purpose for which it was written. It should prove invaluable to students at the London School of Tropical Medicine, and its wealth of fine illustrations will be most helpful to all laboratory workers. It is a most valuable contribution to the study of medical protozoology.

R. KNOWLES.

A MANUAL OF HELMINTHOLOGY, MEDICAL AND VETERINARY.—By H. A. Baylis, M.A., D.Sc. London: Baillière, Tindall and Cox. 1929. Pp. XI plus 303. Text figures 200. Price 30s. net.

A book on the helminth parasites of man and domestic animals has long been wanted, for the only volumes dealing with this subject hitherto available have been books on general parasitology, and with the exception of Brumpt's *Précis de Parasitologie* none of these have been kept up to date. The number of worm parasites of economic importance is now so great that they cannot be dealt with adequately in a general parasitology. The publication of this book is especially opportune, for the protozoologists have been well catered for by the two books on their subject by Wenyon and Knowles, but helminthologists have not been so fortunate in having a book on their specialty until the appearance of the book under review.

The book contains a full list of the helminth parasites recorded from man and domestic animals up to the date of publication, and so it is an excellent landmark from which to begin the investigation of any species of worm found in these animals. In the preface the author lays stress on the fact that he has made the book as short as possible, and although this is a laudable effort it is doubtful if his attempt at abbreviation has not been overdone and thus considerably reduced the value of the volume, especially to the research worker. The most striking omission in this respect is the absence of references and bibliography, which makes it impossible to use the book in making a more detailed study of any species than is supplied by the author. In some instances the descriptions are very meagre, and in consequence the book is only ".....helpful to the reader in obtaining at least an approximate determination of most of the parasites which he is likely to meet," to quote from the preface.

The arrangement of the book is not quite so clear as it might be, as the only headings employed are those of families. Subfamilies, genera, and species are introduced without any special plan; sometimes a paragraph begins with a specific name and sometimes several species are included in the body of a single paragraph; sometimes the name of a species is written in full and sometimes only the initial letter of a genus is used. As an example of a few of the variations employed, the paragraphs on pages 156 and 157 begin as follows. "*Poterlostomum* Quiel, 1919....." "In *Gyalocephalus* Loose, 1900,....." "*G. Capitatus* Looss, 1900,....." "the genus *Bourgetella* is represented by a single species, *B. diducta* Raillet, Henry and Bauche, 1919....." "In the subfamily *Oesophagostominae*...." "In the genus *Oesophagostomum* Molin, 1861....." Although the generic names are usually printed in black type on the first occasion they are used, italics have been employed in a few instances.

In the Trematodes three families, viz., *Schistomatida*, *Echinostomatida*, and *Lepodermatida* are noted. No authorities or dates are given for any families in the book so it is not possible to say where the author has obtained these names. It is not clear why the well established and correctly spelled names, viz., *Schistomida* Looss, 1899, and *Echinostomida*, Looss, 1902 have been discarded. The above three names do not conform to the rules for family formation nor is their spelling consistent with other families, such as *Ancylostomida*, *Anidossontida*, etc., made use of by the author.

In referring to dimensions of worms or of special organs the author impartially describes them as being so many millimetres "in length" or so many millimetres "long."

A few minor omissions have been noted, e.g., *Cryptocotyle lingua* is said to be only found in dogs in America, whereas there is a record of its discovery in England, and *Bertiella studei* is stated to have been only once found in a human being in Mauritius, whereas there is also a record of this worm from a human being in India. Another thing which is not strictly in accord with the facts is to include Australia among the endemic countries in which *Schistosoma haematobium* occurs.

In view of the mass of detailed information contained in the book however, these errors and omissions are very few and of slight importance. The illustrations are numerous, and in addition to many original drawings the author has drawn freely from the literature, but he has never failed to acknowledge the source from which they were obtained. In the opening paragraphs on the general anatomy of Trematodes, Cestodes, and Nematodes, which are obviously written for beginners, it would have been an advantage to have included diagrams of the typical structure of each of these groups.

The book is well printed in clear type and is of handy size, and errors due to type setting are remarkably infrequent. An extremely useful addition is the inclusion of a special index giving the different species of worms recorded from each host, and such a list without any amplification is invaluable to any worker in the subject, and had that been published by itself it would have been an important addition to the literature.

There is no doubt that the book will be of great use to workers in helminthology, and if in a subsequent edition a full bibliography is added it will be invaluable.

P. A. M.

EPIDEMIOLOGY OLD AND NEW.—By Sir William Hamer, M.A., M.D., F.R.C.P. London: Kegan Paul, Trench, Trubner & Co., Ltd. 1928. Pp. X plus 130. Price 9s. net.

THIS is the second important book on epidemiology to be reviewed in this journal within twelve months. In his *Genesis of Epidemics* Col. Gill dealt with many

aspects of the subject as far as it affected India and discussed various theories, but his book was avowedly written with the object of establishing his claims for the unitary mechanism of epidemics and for his "quantum theory." Malaria—the epidemiology of which few people have a greater knowledge of than Col. Gill—was the lay-figure on which he cut his coat: he then demonstrated that this fitted influenza and plague also.

The writer of the book under review had no particular theory to ride, but, as the title suggests, he has given a general review of the epidemiology before the micro-organismal theory of diseases was established, the complete revolution which it underwent with the advance of bacteriology and protozoology, and finally the regressive movement which it is now undergoing with the further advance in our knowledge of bacteriology and our inevitable facing of the fact that the behaviour of epidemics cannot be explained in the laboratory. Sir William Hamer is obviously an advocate of the present day "back to Sydenham" movement. He loves epidemics "for themselves alone," and treats them as epidemics of disease rather than epidemics of one particular disease. An "epidemic constitution" is formed and it appears to be a matter subsequently decided by chance, or the powers above, as to what form it shall take. At the present day the betting is about 100 to 1 on influenza, "the standard fever of Nature."

One is tempted to say that epidemiology is at present in a very unsatisfactory state. A few years ago everything was cut and dry: with our superior knowledge regarding the part played by bacteria in producing disease we scoffed at the nonsense that Sydenham and those fellows used to talk. Now it is just beginning to dawn on us that we cannot assume "that because a writer of the seventeenth and eighteenth century uses words which, used as we use (these) words, seem nonsensical, he was therefore writing nonsense." The old regime has got to pass, though it may not be succeeded by those responsible for its undoing.

We can strongly recommend this book, both to the public health expert and to the student of epidemiology. It is pleasantly written; it is not a mass of dry statistics, though there are a number of useful and graphic diagrams which illustrate the writer's points. The book forms an excellent beginning to that promising series, the Anglo-French Library of Medical and Biological Science.

We have one trivial criticism which we should have withheld had it not touched a very sensitive spot. In his official capacity Sir William Hamer has had to write numerous reports. It is the fashion—one might say invariable custom—in public health reports that all ordinary rules should be ignored and that the names of diseases, wherever they appear in the text, should have a capital initial letter. Sir William Hamer has struggled—not altogether successfully—against this influence. Nearly every page is bespattered with capitals; many of these, though justifiable, are entirely unnecessary; for others it is difficult to find any excuse. He is not altogether consistent; on page 30 he writes "epidemic Encephalitis in Dogs closely resembling Encephalitis lethargica"; on the next page he writes "encephalitis" without its initial capital letter, and further down the page "Encephalitis lethargica." Then again on page 50 we see "the history of Encephalo-mylitis made it abundantly clear that encephalitis lethargica," and finally he bursts into italics with a "a comprehensive report on *encephalitis lethargica*". Influenza is sometimes given an initial capital for no apparent reason (page 31), and the word "epidemiology" is usually, but not always, written with a capital "E."

L. E. N.

THE SACK-'EM-UP MEN.—By James Moores Ball, M.D., LL.D. Edinburgh: Oliver and Boyd. 1928. Pp. XXXI plus 216. Price 16s. net.

In a list of incentives to crime, the law of the land must surely hold a very prominent position. In the United States at the present day a very high proportion of the crimes committed—detected and otherwise—are associated with the evasion of the prohibition laws. Prior to 1832 some of the most spectacular crimes in the United Kingdom were committed on account of the law which allowed only the bodies of executed criminals to be used for purposes of dissection. Nevertheless, anatomy flourished in those days just as the drink trade flourishes in America to-day: the student and doctor had to learn his anatomy and, despite the law, he did it—not openly, but everybody knew that he was doing it. To-day the hospitable prohibitionist Congressman does not openly display his bottle of smuggled whiskey, but his acquaintances all know that when they call he will remove from a bookshelf what appears to be six volumes containing the works of Shakespeare, but which in actual fact is a case containing a very fine selection of alcoholic beverages.

In the book under review Dr. James Moores Ball has given us many details of the history of the study of anatomy and pathology in Europe up to and including the time of the passing of the Anatomy Act in 1832, together with descriptions of many of the crimes that were committed to provide anatomical material. The last chapter gives a very short account of the early study of anatomy and pathology in America and some details of the crimes of the "resurrectionists," both prior and subsequent to the passing of the Anatomy Acts in the United States which, with one exception, were subsequent to 1832.

There is much valuable information collected in this book, but the outstanding feature is the numerous excellent reproductions of old prints and of portraits of distinguished pioneers in the study of anatomy. On the whole the book is uneven; it is more a collection of incidents than a complete history of the subject. Nevertheless, to the library of the student of medical history this book will form an important addition.

For the unnecessarily dysphuistic title there appears to be no excuse and we are surprised that the publishers should have allowed so fine an example of book production to be thus disfigured.

HOSPITALS AND THE STATE: A POPULAR STUDY OF THE PRINCIPLES AND PRACTICE OF CHARITY.—By R. Westland Chalmers, M.B., CH.B., D.M.R.E. London: John Bale, Sons and Danielsson, Ltd. 1928. Pp. IX plus 143. Price 6s. net.

At the present time the general public are more interested than ever before in the hospital systems that exist in England.

All public bodies find that they are responsible for the upkeep of institutions for the care of the sick, and all tax-payers must realise that a proportion of their taxes are spent on these institutions.

With the advance of surgery and expensive, though necessary, methods of diagnosis, many have to go to hospitals who, a few years ago, would have been treated privately.

One finds in the correspondence columns of the medical journals that there is a marked difference of opinion among medical men as to the value of the system so prevalent in England, whereby the workers in the big charitable hospitals are voluntary workers.

There is even a not inconsiderable body of opinion that thinks all hospitals should be financed and organised by the State.

Dr. Chalmers has realised the growing interest that is taken in hospital charities, and he has also realised that this interest calls for a book that will relate in a popular manner the history of the growth of this form of charity.

The book indeed is best described as a short history of hospitals, their origin and growth.

The author describes how the first hospitals were of a domiciliary origin. The Latin word *hospes* denotes both a guest and a host. The "hospice," like that of St. Bernard, was a monastery, and the English monasteries set apart their *hospitium* for the use of guests.

The first institutions that were entirely used for the treatment of the sick were the lazar houses which were distributed throughout Europe in the Middle Ages. From these beginnings the author traces the growth of our modern systems. The effect of religious, political, and economic causes is explained.

The book is very well written and well printed, and should appeal to all who are interested in the history of philanthropy.

ACUTE INFECTIOUS DISEASES.—By Jay Frank Schamberg, A.B., M.D. and John A. Kolmer, M.Sc., M.D., Dr. P.H., D.Sc. LL.D. 2nd edition, thoroughly revised. London: Henry Kimpton. 1928. Pp. 888. Illustrated with 161 engravings and 27 full-page plates. Price 50s. net.

HERE we have a large book which deals entirely with those infectious diseases that are common in temperate climates.

The authors have drawn on their long experience of these diseases in Philadelphia, and all their descriptions and conclusions are based on this experience.

Following on an introduction in which infection and immunity are discussed, the authors give us an exhaustive history and description of vaccinia. This is a very important chapter. The statistics that show the value of vaccination are incontrovertible, and it is amazing that, with all the evidence available, there should still be many who do not believe in this method of protection from a terrible disease, and a flourishing anti-vaccination society in England.

The following quotation would probably apply with equal force to those hospitals in India where smallpox is treated: "In the Philadelphia Hospital for Contagious Diseases, during a period of thirty-four years in which time over 9,000 cases of smallpox were treated, we have not had a physician, nurse or attendant, who had been successfully vaccinated or revaccinated prior to going on duty, contract the disease."

The chapter on smallpox is of more interest than any other to practitioners in this country. The disease is very fully described and profusely illustrated.

One turns with interest to that part which deals with the treatment of the disease in the hope of finding something new, but it is not to be found.

The methods of treatment of the various symptoms as they arise are excellently described, but they remain purely symptomatic methods.

The authors have found no value in the red light or convalescent serum treatment of smallpox.

Scarlet-fever is a very common, and frequently a serious, disease in countries with a temperate climate. In India it is comparatively rare. It is described at length, and it is pointed out that the Dick test for immunity in this disease is not of the same importance and significance that it is in diphtheria.

The chapters on measles, rubella, typhus, mumps, whooping-cough and Vincent's angina do not call for special notice; in them each disease is fully and adequately described.

The chapter on diphtheria is more important, and a very excellent account of this disease in all its phases is given. The reviewer believes that in India the antitoxic serum is given most frequently subcutaneously. The authors point out that intramuscular injections are greatly preferable, the absorption being three to four times more rapid. In all very severe cases, when there are no technical difficulties, they give the serum intravenously.

Cerebro-spinal meningitis is quite common in India, although it does not seem to appear in epidemics. The authors advise that the serum should be given intra-spinally by gravity. It is useless to give it intravenously. As much as possible should be given, an equivalent amount of cerebro-spinal fluid being withdrawn. In an adult this should be 40 c.c.

This book of nearly 900 pages describes fourteen acute infectious diseases. Two of these, Flatow Duke's disease and erythema infectiosum, are very uncommon. The others all occur in India, and smallpox and diphtheria are more frequent here than in America.

Typhoid, plague, cholera, relapsing fever and the many short fevers of the dengue type, do not come within the scope of the authors' work. These are the infectious diseases that are of the greatest importance to us. The time has not yet come when an account of the infectious diseases of India can be described by any one authority in one volume.

This book should be of value to all who are in charge of an infectious disease hospital, and will always be of great help to those who have to treat these cases during the ordinary routine of their work.

ELEMENTARY MEDICINE IN TERMS OF PHYSIOLOGY.—By D. W. Carmalt Jones, M.A., M.D., F.R.C.P. London: H. K. Lewis and Co., Ltd. 1929. Pp. VII plus 360, with 4 illustrations. Price 12/6 net.

THE principle upon which this book is founded is unquestionably a sound one, viz., the interpretation of clinical signs and symptoms in terms of disordered physiological processes. For, of a surety, to him who knows his physiology all things clinical shall be added. No attempt is made to cover the whole field of medicine; as the author points out in his introductory chapter "it (i.e., the book) is only intended for beginners, and seeks to point out a few essentials and salient points in order to give some idea of the scope and limitations of the subject." On the whole, the book fulfils this function admirably, and any criticism the reviewer has to offer is concerned essentially with minor points.

The statement (on p. 7) that alcohol is "an irritant poison, producing fibrosis or cirrhosis, particularly in the liver" will not meet with general acceptance. The part played by alcohol in the causation of cirrhosis of the liver is undoubtedly much exaggerated. Actually, the commonest effect of alcohol on the liver is an extreme fatty infiltration. The expression "round cell infiltration" (on p. 10) used to include apparently the cellular exudate occurring in all types of inflammation is apt to be misleading. The expression in question is not ordinarily applied to the predominant cell occurring in pyogenic inflammation, viz., the polymorphonuclear leucocyte.
